Tracheostomy in a thoracic surgical unit

D. B. CLARKE

From Harefield Hospital, Harefield, Middlesex

The first authenticated instance in which tracheostomy was performed was in 1546 when Brasavola (Guthrie, 1944) relieved respiratory obstruction in a patient who was probably suffering from Ludwig's angina. From then until the second world war obstruction of the upper respiratory passages remained the sole indication for this operation. It was a procedure regarded with distrust, being in fact referred to as 'the scandal of surgery', but in recent years its indications have been extended, its potentialities more precisely defined, and its limitations more critically appraised. In this study an analysis has been made of the tracheostomies performed during the past five years in a thoracic surgical unit. This unit consists of 87 beds which also serve general medical and chest wards.

CLINICAL MATERIAL

INDICATION FOR TRACHEOSTOMY A total of 69 tracheostomies were performed in five years. Of these, 52% followed lung resections; the remainder were carried out after cardiac and oesophageal surgery, in patients with respiratory failure who had been referred from the medical wards, for respiratory obstruction, chest injury, and in unconscious patients who were incapable of coughing (Table I). In other series the most frequent indications have been head and chest injuries and paralysis of the muscles of respiration (Nelson, 1958; Head, 1961; Meade, 1961; Watts, 1963).

The patients referred by physicians had gross destruction of lung tissue resulting from chronic bronchitis and emphysema or tuberculosis, and as a result of superadded infection or spontaneous pneumothorax they had progressed to a state of respiratory failure with carbon dioxide retention.

Four tracheostomies were performed for less precisely defined conditions which included myasthenia gravis, the rupture of an empyema into the bronchial tree, and in two cases malignant cachexia (Table I).

The indications for tracheostomy are retention of sputum because of an ineffective cough, inadequate ventilation of the lungs, obstruction of the airway above the tracheal level, and after cardiac surgery (Table II). Björk and Engström (1955) suggest that an arterial PCO₂ above 70 mm. Hg is a strong indication for tracheostomy, but in this series we have been guided by the clinical signs of hypercapnia, i.e., shallow respiration, stupor, a hot flushed skin with an elevated blood pressure, and a bounding pulse. In a patient who showed signs of sputum retention, tracheostomy was usually deferred until physiotherapy had been given an adequate trial or bronchoscopic aspiration of secretions had failed to provide more than temporary relief. The timing of the operation is important. There is little to be gained from persisting with physiotherapy when it becomes obvious that nothing is being achieved other than the exhaustion of the patient. There is a large measure of truth in the adage that the right time to perform tracheostomy is when the likelihood of its being necessary is first suggested.

Intermittent positive pressure ventilation using a mechanical respirator was used in 21.8% of cases. The conditions in which tracheostomy was performed are detailed in Table I and the indications for tracheostomy in these conditions are given in Table II.

TRACHEOSTOMY IN LUNG RESECTIONS An analysis of the 36 lung resections shows that 50% of the tracheostomies in this group followed left

pneumonectomy (Table III). In nearly half of these there was evidence of damage to the left recurrent laryngeal nerve which must have been sustained when the sub-aortic lymph nodes were excised. Right pneumonectomy accounted for 25% of the total, and lobectomies for the remaining 25% (Table III).

</table>

Sputum retention was the commonest indication. In these cases an inadequate cough resulted from general weakness, pain or paralysis of one vocal cord. Ventilatory inadequacy, the next commonest cause, resulted from poor function of the residual lung, shallow respiration because of pain or weakness, and from paradoxical movement either of the chest wall, when part of this had been excised, or of the diaphragm when the phrenic nerve had been damaged at operation (Björk and Engström, 1955; Minnis and Griffin, 1961). When pre-operative lung function studies indicated a marginal respiratory reserve elective tracheostomy was carried out at the time of operation in three instances.

By preventing the build-up of intra-bronchial pressure before explosive decompression in the act of coughing, tracheostomy may be used electively to take some of the strain from a doubtful bronchial suture line after pneumonectomy. It may be indicated for the same reasons after sleeve resection, with the added incentive that marginal respiratory function may well have been an indication for such a procedure and that the residual lung on the side operated upon is peculiarly liable to sputum retention. The development of a bronchopleural fistula with spill-over into the contralateral lung has been a further indication in two instances in this series.

TRACHEOSTOMY IN OTHER CONDITIONS The value of early tracheostomy in major chest injuries has been established.

There are only two cases in this series because this hospital is not served by a casualty department. Both had paradoxical movement of the chest wall, and in each the mere performance of tracheostomy reduced the paradox to such a degree that positive pressure respiration was unnecessary.

The six cases of airway obstruction were due to malignancy at laryngeal level, Ludwig's angina, and laryngeal oedema.

Tracheostomy is of value in respiratory failure in patients with gross diminution of pulmonary function for three reasons: by reducing the dead space by approximately 100 ml. the alveolar ventilation is nearly doubled; when carbon dioxide retention is established, assisted ventilation with a mechanical respirator not only washes out excess CO₂ but also corrects anoxia; the excessive bronchial secretion usually found in these patients can be effectively sucked out.

Tracheostomy combined with intermittent positive pressure respiration may assist patients subjected to cardiac surgery in several ways. It
ensures adequate oxygenation at all times in a
group of patients in whom anoxia can be critical
or even fatal. In the resting subject, about 25% of work done by the heart is expended in the
mechanical work of respiration. In mitral valve
disease this figure may be more than doubled. It
follows therefore that by taking over respiration
with a ventilator this burden is largely removed
from the heart. Further, the increase in gas
tension in the alveoli produced by I.P.P.R. tends
to counteract those forces which produce pulmonary oedema. It has been the practice in this
unit of late to carry out an elective tracheostomy
in patients with mitral incompetence who have a
high left atrial pressure after surgery, and
routinely after total correction of Fallot's
tetralogy.

Mortality On first inspection, an overall
mortality of 42% is alarming and liable to obscure
the very real value of tracheostomy. Of these 29
deaths, however, 15 were from unrelated
causes, such as pulmonary embolus, carcino-
matisis or haemorrhage, which could not be
attributed to the tracheostomy; nor could these
deaths be expected to have been avoided because
traceostomy had been performed.

Of the remaining 14 deaths, eight (57%) were
attributable to bronchopneumonia (Table IV). Watts (1963) reports a mortality of 2%, but the
causes of death were directly attributable to the
operation itself and do not include broncho-
pneumonia. Of his 212 cases, 37 came to post-
mortem examination, and in 26 of these there was
evidence of bronchopulmonary infection; in 16
this was thought to be the cause of death. It will
be argued that some of these infections were the
inexorable progress of the condition for which the
tracheostomy was done in the first place, but
Gotsman and Whitby (1964) carried out bacterio-
logical studies in a group of 29 patients who
underwent tracheostomy and these cast a disquiet-
ing light on this matter. Of their 29 patients, six
died within three days and were excluded from
the study. Of the remaining 23, 19 developed the
clinical signs of infection. The infecting organism
cultured from the trachea was in no case the same
as those present in the sputum before tracheo-
stomy; 11 were infections with penicillin-
resistant staphylococci and five were due to
*Pseudomonas pyocyanea*. Their studies showed
that these organisms were derived from the
hospital environment. They must have been
introduced into the trachea either by the suction
catheter or from the patients' own skin. In two
cases, death resulted from bronchopleural fistula
and in four from respiratory failure. Six patients
had tracheostomy performed after having
sustained an injury to the recurrent laryngeal nerve
at left pneumonectomy; five of these died. There
were no immediate deaths in the group which had
airway obstruction above tracheal level. The fact
that five out of nine patients who would inevitably
have died from respiratory failure due to
degenerative lung disease with superadded infec-
tion were saved is sufficient proof of the efficacy
of tracheostomy in this condition.

The highest mortality in lung resection was in
the left pneumonectomy group (eight deaths).

If mortality is correlated with the day after
operation on which tracheostomy was performed,
it is evident that those in whom difficulties were
anticipated by the performance of an elective
tracheostomy at the time of operation did best
(one death in six elective tracheostomies).
Thereafter there is little difference in mortality between
those in whom the need for tracheostomy became
evident on the first post-operative day or on the
fifth. The fact that six out of seven tracheostomies
performed as an emergency at the time of operation
were followed by death is a reflection of the
gravity of the condition for which they were carried out, e.g., after cardiac arrest.

A total of 49 tracheostomies were performed
after operation with an overall mortality of 45%.

No single indication is more likely to result in
death than any other; the survival figures after
tracheostomies performed for respiratory insufficiency and sputum retention are the same
(Table V).

Table VI shows the age distribution in this
series.

is sutured to the inferior margin of the transverse skin incision. A vertical incision may be preferred in infants. The flap acts as a guide to direct the tube into the trachea and facilitates changing. It also circumvents the complication sometimes encountered with a simple tracheal stoma in which the tube rides out of the stoma and comes to lie in front of the trachea. We have largely discarded the metal tubes for those made of plastic except occasionally for children when the larger bore obtainable with a metal tube is an advantage. Watts (1963) condemns these portex tubes on the grounds that they are difficult to keep clean and may even become completely blocked by thick mucus. We have found that the flap so facilitates the changing of tubes that it is possible to insert a fresh one every two or three days. However, one avoidable death in this series was attributable to complete blockage of the tube.

It is sometimes argued that the flap tracheostomy gives rise to tracheal stenosis. In no case in which a flap was fashioned did this complication occur; the only case of stenure occurred in a child in whom a large circular stoma had been made which became adherent to both the superior and inferior margins of the wound. The trachea became buckled forwards until it resembled a double-barrelled colostomy (Fig. 2a). We feel that damage to the first ring of the trachea or the creation of a too generous stoma are more important factors in the genesis of stenure. In no patient did bleeding from the tracheostomy incision give rise to difficulties, and all incisions closed satisfactorily two or three days after the tube was removed.

In one case a thick neck resulted in the trachea being at a greater depth from the skin than the length of the horizontal part of the tube. In these circumstances the tube may either refuse to lie in the trachea or it may angle so that its tip is pressed against the anterior tracheal wall with ulceration of the mucous membrane (Fig. 2b). An endotracheal tube, with its more gentle curve, may be more satisfactory in these circumstances; a flange may be improvised from rubber tubing. If the stoma is placed too far down the trachea, two difficulties are encountered. As the trachea slopes backwards a low stoma is at a greater depth from the skin than a higher one. Consequently the circumstances just described may occur in which the tip of the tube may impinge on the anterior wall of the trachea with resulting trauma to the mucous membrane. Further, a low tracheostomy carried out with the head extended may result in a stoma half-way down the trachea. After operation this will be found to lie behind

**DISCUSSION**

The evaluation of any surgical procedure must stem from a balance of the benefits to be obtained against the hazards which may be incurred. Tracheostomy is a life-saving operation. The relief of respiratory distress in a patient drowning in his own bronchial secretions or the return to consciousness of a patient narcotized by carbon dioxide can be dramatic. However, an awareness of some of the disadvantages inherent in tracheostomy is essential if a successful outcome is to be achieved.

**TECHNICAL CONSIDERATIONS**

The method of performing this operation favoured in this unit is to cut a tracheostomy flap in the anterior wall of the trachea at the level of the second and third rings (Fig. 1). This is turned forward and its free edge

---

Tracheostomy in a thoracic surgical unit

POST-OPERATIVE MANAGEMENT There are certain disadvantages inherent in the exclusion of the upper respiratory passages. It is imperative that inspired air should be adequately humidified if secretions are not to become so viscid that they impede the normal ciliary action of the respiratory epithelium and make adequate tracheal toilet almost impossible. Of late, a commercially produced humidifier connected to a Perspex box which fits over the tracheostomy has been used, but acceptable humidification may be obtained by inserting a fine needle connected to a slow saline drip into an oxygen catheter which is placed in the mouth of the tube. Once formed, viscid secretions may be thinned by the intratracheal injection of 2 or 3 ml. of sodium bicarbonate solution.

It is significant that the greatest single cause of death in this series is bronchopneumonia, and it is difficult not to believe that infection introduced by way of the tracheostomy may play a part in this. For this reason an aseptic ritual must be observed during tracheal toilet. A fresh sterile suction tube, handled with forceps, should be used each time. It is only by regarding the repeated intubation of the trachea with the respect usually accorded to repeated intubations of the bladder that infection can be avoided. In one patient an ulcer 1 cm. in diameter was found just to the right of the carina, at the point where the tip of an aspirating catheter might be expected to impinge (Fig. 2d). We now use a 'Y' tube inserted in the suction line so that suction may be controlled by occluding the open limb of the 'Y' with the thumb. Suction is not applied until the catheter has passed through the tracheostomy tube, otherwise difficulty is experienced because of the tip of the catheter sticking to the walls of the tube (Plum and Dunning, 1956). Undue force and

FIG. 2. Some mechanical complications of tracheostomy: (a) Forward buckling of the trachea; (b) ulceration of the anterior tracheal wall; (c) surgical emphysema due to displacement of the tube; (d) ulceration of the carina by suction catheter; (e) bronchial stump fistula; (f) herniation of over-inflated cuff; (g) detachable cuff left in trachea; (b) necrosis of tracheal rings due to cuff pressure; (i) trauma to posterior wall of trachea.
needed prodding with the catheter is to be deprecated. It is significant that two cases of bronchopleural fistula occurred after tracheostomy following right pneumonectomy. This may well have resulted from trauma to the bronchial stump by the suction catheter, and in one instance such a fistula after pneumonectomy led to sudden death as the pneumonectomy space contents spilled into the opposite lung (Fig. 2e).

This study underlines the fact that injury to the recurrent laryngeal nerve at operation may have serious consequences. Left pneumonectomy accounted for 50% of cases in which tracheostomy was necessary after lung resection, and, of the eight deaths that occurred in this group, there was definite evidence of a paralysed vocal cord in five.

INTERMITTENT POSITIVE PRESSURE RESPIRATION
This is one of the most useful indications for tracheostomy. While an indwelling endotracheal tube is acceptable for a time, we are reluctant to persist with this for longer than 24 hours because of the risk of trauma to the vocal cords and we usually proceed to tracheostomy if the need for intermittent positive pressure respiration is likely to be prolonged.

Trouble was experienced with the inflatable cuff in three instances. In two of these, an over-inflated cuff herniated over the end of the tracheostomy tube (Fig. 2f), and in one the inflatable cuff was left in the trachea when the tube was removed (Fig. 2g). It immediately produced complete tracheal obstruction. It is urged that at no time should the cuff be inflated with a greater volume of air than that necessary to produce an airtight fit, and if a removable inflatable cuff is used it should be securely stitched to the tube before insertion. Over-inflation may also lead to necrosis of the cartilaginous rings of the trachea (Watts, 1963) (Fig. 2h). Another danger is encountered if an inflatable cuff is attached to a silver tube; the weight of tubing from the ventilator may angle the tracheostomy tube so that its tip damages the posterior wall of the trachea, and perforation of the oesophagus from this source may occur (Fig. 2i).

To admit that there are certain hazards inherent in tracheostomy is not to detract from its value. It is an operation with well-defined indications, to be performed deliberately under good conditions before delay has led to the necessity for performing a hurried procedure on a moribund patient. Responsibility does not cease with the completion of the operation. For a successful outcome, conscientious post-operative management is essential.

SUMMARY
Tracheostomies performed in a thoracic surgical unit over a period of five years are examined according to the indications for which they were carried out, and the deaths which resulted are analysed. The technique of the performance and the management of tracheostomy current in this unit are described, and certain difficulties and hazards are enumerated. The importance of adequate humidification and efficient tracheal toilet is stressed if bronchopneumonia is to be avoided.

I am grateful to the consultant staff of Harefield Hospital for permission to refer to the records of their patients and to Sir Thomas Holmes Sellors, Mr. J. Leigh Collis, and Mr. J. K. Ross for much helpful advice in the preparation of this paper.
