Dead space ventilation in normal children and children with obstructive airways disease

A. A. KERR

Respiratory Unit, The Hospital for Sick Children, Great Ormond Street, London

Kerr, A. A. (1976). Thorax, 31, 63-69. Dead space ventilation in normal children and children with obstructive airways disease. Anatomical dead space was measured in 72 normal children aged from 5 to 16 years, using the single breath method. There was a linear increase in this measurement with height, weight, and end-inspiratory lung volume.

Physiological dead space was measured in 52 normal children using the Bohr equation and substituting a rebreathing Pco₂ for alveolar Pco₂. There was a parallel increase in this measurement with height, weight, and end-inspiratory lung volume. The difference between the two dead space measurements constitutes the alveolar dead space and was constant over the whole age range at 45±22 ml.

The ratio of physiological dead space to tidal volume was 33.6±4.6% and was unaltered by age or change in lung volume.

The effect of airways obstruction on the dead space volumes was studied in 36 children with asthma and 28 with cystic fibrosis. Physiological dead space increased with increasing airways obstruction. Anatomical dead space remained constant in spite of marked increases in lung volume associated with the airways obstruction.

There is little published information on the various dead space volumes in children (Polgar and Promadhat, 1971). Hart, Orzalesi, and Cook (1963) measured the anatomical dead space in 73 normal subjects aged 4 to 42 years. No information is obtained from these data on the age range (Radford, 1955) are based on derived data from eight boys only (Robinson, 1938).

Similarly, there is little information on the physiological dead space in normal children and on the ratio of this to tidal volume (Beaudry, Wise, and Seely, 1967; Levison, Featherby, and Weng, 1970).

The following studies were undertaken to collect more normal data and, in particular, to compare anatomical and physiological dead space.

A study was also made of the changes in dead space volumes with airways obstruction due to asthma and cystic fibrosis.

METHODS AND MATERIAL

Studies were performed on 72 normal healthy children aged 5 to 16 years. They were all from the inner London area and were well at the time of study. All measurements were made with the child sitting on a laboratory stool under resting conditions.

Anatomical dead space (\(V_{d\text{,anat}}\)) was measured by a modification of the single breath method (Fowler, 1948). The electronically integrated expired volume from a Fleisch No. 1 pneumotachograph and the expired \(\text{CO}_2\) concentration from a VG Micromass I mass spectrometer were recorded on a U-V recorder for at least three breaths. The dead space was measured from the point where the \(\text{CO}_2\) concentration had risen halfway to the initial alveolar level (Young, 1955). Allowance of 150 ms was made for the delay in gas analysis, and a further 15 ml was subtracted for apparatus dead space. The pneumotachograph was calibrated by injecting through it 500 ml from a large syringe.

The accuracy of this method of analysis was checked in 10 normal children, 10 children with asthma, and 10 with cystic fibrosis. This was done by drawing a perpendicular through the halfway point on the \(\text{CO}_2\) trace and measuring the areas A and B on the trace as shown in Figure 1. Ideally, these areas should be equal. They were cut out and weighed, and the error in placing the perpendicular was estimated in terms of displacement to either side of ideal. There was an overall mean shift of 0.14 mm to the left for this perpendicular. Even with the greatest
displacement, however, there was no measurable underestimation of the volume of \( V_{D \text{ anat}} \). The method was further checked by injecting a \( CO_2 \) mixture through an added dead space and comparing the recorded \( V_D \) of this with the actual added volume measured by filling it with water. There was a 1% overestimate for an added dead space of 95 ml and a 9% overestimate for a 64 ml dead space. The mean coefficient of variation for \( V_{D \text{ anat}} \) measurement in 12 children who had five or more breaths analysed was 10.1%.

The physiological dead space (\( V_{D \text{ phys}} \)) was measured using the Bohr equation (Comroe et al., 1962). An accurately timed mixed expired gas collection was made over at least 3 minutes. The volume was measured by the pneumotachograph. This was calibrated immediately after the collection by taking a second collection through it into a wet spirometer (C. F. Palmer Ltd, London), the volume of which was measured and corrected to BTPS. The \( CO_2 \) and \( O_2 \) content of the final mixed expired gas collection was measured with the mass spectrometer. The end-tidal \( P_{CO_2} \) was recorded during the collection, and if this varied by more than 5%, the collection was discarded. Alveolar \( P_{CO_2} \) was measured indirectly by a rebreathing method using mixtures of \( CO_2 \) in air (Collier, 1956). Tracings were accepted only if a true \( CO_2 \) equilibration plateau was obtained between 10 and 20 seconds from the start of rebreathing. Duplicate estimates were made, and from these the mixed venous \( P_{CO_2} \) was obtained; 6 mmHg was subtracted to give the arterial \( P_{CO_2} \), which was assumed to equal alveolar \( P_{CO_2} \). The mean arterial \( P_{CO_2} \) measured by this method in 52 normal children was 39.3 mmHg with a standard deviation of 3.1 mmHg. The coefficient of variation for \( V_{D \text{ phys}} \) measurement was 6.0% in one adult tested four times.

During the 3 minute collection for the measurement of \( V_{D \text{ phys}} \), minute ventilation (\( \dot{V}_E \)), tidal volume (\( V_T \)), and breathing frequency (\( f \)) were recorded. From these, alveolar minute ventilation \( (\dot{V}_A = \dot{V}_E - \dot{V}_{D \text{ anat}}) \) and alveolar dead space \( (V_{DA} = V_{D \text{ phys}} - V_{D \text{ anat}}) \) were calculated.

Thoracic gas volume (TGV) was measured by the plethysmographic method of Dubois et al. (1956). End-inspiratory lung volume (EILV) was taken as the sum of TGV and \( V_T \).

RESULTS

Anatomical dead space (\( V_{D \text{ anat}} \)) measurements were obtained in 72 normal children and the results are illustrated in Figure 2.

There were 52 children in whom a satisfactory steady-state gas collection with constant end-tidal \( P_{CO_2} \) was obtained. Data from these children only were included in results of \( V_{D \text{ phys}} \) and ventilation

![Figure 1](http://thorax.bmj.com/)

**FIG. 1.** Tidal volume trace (\( V_T \), above) and expired \( CO_2 \) trace (below) showing the method used to measure anatomical dead space (\( V_{D \text{ anat}} \)). Ideally, the triangular areas A and B should be equal. In this study the perpendicular between the two areas was drawn so that it crossed the \( CO_2 \) trace halfway between 0% \( CO_2 \) and the initial alveolar \( CO_2 \) concentration. Using this method there was no significant difference in the areas. D is the delay due to the sampling time of the \( CO_2 \) analyser.

![Figure 2](http://thorax.bmj.com/)

**FIG. 2.** Anatomical dead space (\( V_{D \text{ anat}} \)) plotted against height for 72 healthy children. The regression line and 2 standard deviations from the regression are shown.
measurements. The results of $V_D_{phys}$ measurement in this group of children are shown in Figure 3.

EILV is the most appropriate lung volume to which to relate $V_D$, as it represents the actual lung volume from which $V_D$ is measured. The regression equations and correlation coefficients for all these data are given in Table I.

There was no significant difference in the slopes of the regression lines for $V_D_{anat}$ and $V_D_{phys}$ ($r > 0.05$), and the mean difference between them was 44·5 ml.

Table II shows the mean values for $f$, $Paco_2$, $R$, $V_D_{anat}/VT$, $V_D_{phys}/VT$, $V_D_{anat}$ and $V_D_{anat}/V_A$. None of these varied significantly with age.

Tidal volume ($V_T$) showed a linear relationship to height:

$$V_T(\text{ml}) = 4.19 \times \text{Height (cm)} - 206.6 \ (r = 0.596)$$

Alveolar ventilation also had a significant correlation with height:

$$V_A(l/min) = 0.034 \times \text{Height} + 0.395 \ (r = 0.548).$$

Satisfactory data were obtained in 36 children with bronchial asthma, in eight of whom second measurements were obtained at a time when the degree of airways obstruction had altered. In the total group of asthmatic children, $V_D_{anat}$ remained at the volume expected for height but was diminished in relation to EILV (Fig. 4). The diminution relative to lung volume was greater with more severe degrees of hyperinflation. These findings were consistent with those in the eight children in whom serial studies were performed. In spite of a mean increase in EILV of 604±348 ml (1SD), there was an increase in $V_D_{anat}$ of only 0.63±11·2 ml (1 SD). By contrast, the rise in $V_D_{phys}$ was either in proportion to the rise in lung volume or greater than would be expected (Fig. 5).

Anatomical dead space (VD anat) plotted against end-inspiratory lung volume (EILV) in 28 children with cystic fibrosis. The degree of hyperinflation is indicated by the increase in thoracic gas volume (TGV), which is shown as a percentage of that predicted for height. The mean ±2 SD lines are shown for the regression of VD anat against EILV in healthy children.

DISCUSSION

It has been shown that the respiratory dead space measured by relating expired gas concentration changes to expired volume (VD anat) is the same for all respiratory gases (Bartels et al., 1954). It is, therefore, reasonable to compare the values of VD anat obtained in the present study with earlier data using the original nitrogen technique (Fowler, 1948). The only data available over a similar age range are from studies by Hart et al. (1963) and Beaudry et al. (1967). These results are shown in Figure 8. The data on adult males from Fowler (1948) are also shown for comparison. The results from other studies tend to fall between the regressions for the two different measurements of VD in the present study. An apparent decrease in VD anat can occur with breath-holding (Bartels et al., 1954; Shepard, Campbell,
Dead space ventilation in normal children and children with obstructive airways disease

![Graph showing comparison of dead space (V_D) measurement in healthy subjects. The values from Fowler (1948) are the mean and 2 SD for 45 adult males using the N_2 single breath method. The other data are from Beaudry et al. (1967), using the Bohr equation in children, and from Hart et al. (1963), using the N_2 single breath method in children and adults.](http://thorax.bmj.com/)

FIG. 8. Comparison of dead space (V_D) measurement in healthy subjects. The values from Fowler (1948) are the mean and 2 SD for 45 adult males using the N_2 single breath method. The other data are from Beaudry et al. (1967), using the Bohr equation in children, and from Hart et al. (1963), using the N_2 single breath method in children and adults.

Martin, and Enns, 1957). Alternatively, increasing the breathing frequency may cause an apparent increase in V_D anat, and a real increase in V_D anat occurs with increased lung volume (Shepard et al., 1957; Lifshay, Fast, and Glazier, 1971). From the data available, none of these factors appears to contribute significantly to the variation in V_D results between the present study and earlier work.

It is accepted in adults that V_D anat and V_D phys are virtually identical in normal lungs (Comroe et al., 1962). That a similar relationship holds for children has been assumed (Polgar and Promadhat, 1971), but no direct measurement of both types of dead space in the same children has previously been made. The present study shows a mean difference of 44·5 ml between the regression lines for V_D anat and V_D phys. This difference (V_D anat) remains constant with age, and it might be expected to become a smaller proportion of V_A in older children. This does not appear to be so. V_D anat/V_A shows no correlation with age, height or lung volume, presumably because there is a wide variation in V_D anat measurement.

The use of 6 mmHg as the a–V difference for PCO₂ has recently been questioned by McEvoy, Jones, and Campbell (1974). They found that 10 mmHg was a more appropriate figure in adults with normal PCO₂ and when the blood was fully oxygenated. The Collier method for rebreathing PCO₂, as used in the present study, uses a mixture of CO₂ in air. At equilibration the O₂ content of the bag was about 16% so that Hb would not be fully saturated. In these circumstances the PCO₂ would be lower than if it were saturated, provided the CO₂ content remains constant. Accordingly, the a–V difference for PCO₂ would be expected to be lower in the present study than in the work of McEvoy et al. (1974). This is borne out by the fact that the range of Paco₂ in these normal children, as estimated by the rebreathing method, is the same as is generally accepted for direct measurement. However, in children with airways obstruction, the a–V difference may have been greater than 6 mmHg and, if so, this would result in an overestimate in estimated Paco₂ and V_D phys in this group.

The ratio of wasted ventilation to tidal volume (V_D phys/VT) has been cited as a useful index in intensive respiratory management (Downes, Fulgencio, and Raphaely, 1972) and as a sensitive index of early changes with disease, especially during exercise challenge (Levine et al., 1970). A normal value of 30% is usually quoted for this ratio (Polgar and Promadhat, 1971). The values obtained in the present study show a wide range, which is comparable to data reported in studies on normal infants, older children, and adults (Table III).

Recently, Harris et al. (1973) pointed out the inapplicability of relating V_D phys to VT only. In their study in adults, they defined a multiple regression of V_D on age, height, VT and the reciprocal of respiratory frequency which gave the best prediction of V_D phys. In the present study a similarly improved correlation was obtained by using simple regressions of V_D phys on height, weight, and lung volume (EILV) rather than the ratio of V_D phys to VT.

There is a significant correlation between VT and height, and these data agree with those of Levison et al. (1970). The estimated figures given by Cook and Motoyama (1968) are too low. The alveolar ventilation data (V_A) from this study are significantly higher than the measurements of Levison et al. (1970) and the estimates of Cook and Motoyama (1968). Both VT and V_A are increased if not taken under basal conditions, and this probably accounts for the discrepancies. The normal values for the respiratory quotient (R, Table II) indicate that this increase in ventilation was appropriate to the increase in oxygen consumption above the basal state.

The changes in V_D with disease are of considerable interest. It is well established that V_D phys is increased in both asthma and cystic fibrosis (Downes et al., 1972). Comparison of Figs. 5 and 7 shows that in cystic fibrosis the V_D phys increase is less dependent on the degree of hyperinflation (as shown by the rise in EILV) than it is in asthma. This is presumably
because cystic fibrosis is a patchy disease (Bodian, 1952), and consequently there is a localized increase in VD phys. In asthma, on the other hand, there is more diffuse airways obstruction, resulting in diminished VA without gross ventilation:perfusion inequality until hyperinflation is severe (TGV more than 150% predicted, in Fig. 5).

The changes in VD anat are different. In asthma, the individual VD anat values are all within the normal range for height but are low in relation to EILV. In normal lungs, increased lung volume causes an increase in VD anat (Shepard et al., 1957; Lifshay et al., 1971). This did not occur in those patients in whom the increased lung volume was due to airways obstruction. There are two possible explanations for this:

1. In asthma, narrowing of the small airways produces poor alveolar emptying during expiration. This results in air trapping at alveolar level with increase in the total lung volume. Such an increase in lung volume is not associated with reduced intrapleural pressure and increased radial traction on the large airways, as occurs when a person with normal lung mechanics increases his lung volume. Consequently, the asthmatic with hyperinflated lungs will tend not to have increased large airway volume.

2. During attacks of asthma, the smooth muscle in the tracheal and bronchial walls also contracts. Olsen, Stevens, and McIlroy (1967) showed in cats that this results in reduced airway wall compliance. This would reduce the effect that breathing at a higher lung volume has on VD anat by preventing the expansion of the large airways that normally occurs with increase in lung volume. From the present data it is not apparent which of these factors is the more important.

I am very grateful to Dr. D. Hatcher for helpful advice during the course of these studies.

The work was supported by a grant from the Medical Research Council.
