Nandi, P. (1977). Thorax, 32, 5–6. Surgery of isolated patent ductus arteriosus: a new technique of suture and division. Since mid-1973 29 cases of isolated patent ductus arteriosus were treated in the Hong Kong University surgical unit with a new technique of suture and division. This technique has almost eliminated the problem of intraoperative haemorrhage and its consequences.

Gross and Hubbard (1939) were the first to report successful ligation of a patent ductus arteriosus. Since then the value of operative treatment of this condition has been universally accepted. Division and suture of the ductus seems to be the method of choice in many centres. When using the standard technique of dividing the ductus between clamps, followed by suturing, the main danger is intraoperative bleeding. In this new technique the ductus is sutured in continuity before division. The use of this technique reduces the risk of operative haemorrhage.

Description of the technique

The initial steps of exposure and dissection of the ductus are the same as in the standard operation of division and suture. Touroff’s (1942) technique of dissecting the ductus is usually followed. When the ductus has been cleared all round, two pairs of Cooley’s ductus clamps are applied, one close to the pulmonary artery and the other close to the aorta. Two separate rows of continuous horizontal mattress sutures are inserted between the two clamps as far apart as possible using 16 mm round-bodied double-armed 4/0 polypropylene sutures, starting with the side of the ductus furthest from the surgeon (Fig. 1). When both rows of horizontal mattress sutures are in place the four needled ends of the sutures are held up to avoid any loose loop in the ductal area. The ductus is then divided between the two horizontal suture lines (Fig. 2), and the same needles are used to suture the cut ends with a continuous over-and-over stitch (Fig. 3). Initial placement of the horizontal mattress sutures prevents the divided ductal ends from slipping. These horizontal mattress sutures also provide a stronger hold for the final over-and-over stitching. There has been no problem of leakage from the stitch holes.

This technique has been used in both small and large ducts in children and adults without difficulty. There may be a criticism that while the ductus is being divided one of the sutures may be

Fig. 1 Ductus dissected: continuous horizontal mattress sutures being applied between two ductus clamps.
Advantages of the new technique

By suturing the ductus in continuity before dividing it one can minimise the problem of bleeding and its consequences. If there is bleeding, especially from the pulmonary end of the divided ductus, the recurrent laryngeal nerve, which may be included in stitches that are applied blindly to control the bleeding, is in jeopardy. The initial suture lines prevent the divided ductal ends from retracting under the clamps. They also provide a firm hold for the final over-and-over stitching, which is particularly important if a ductus is friable from atheromatous change or previous infection.

Results

This technique of 'suture, division, and suture' has been used in 29 patients since the middle of 1973. The ages of the patients ranged from 2 months to 33 years. There were 19 children and 10 adults. The size of the ductus varied from 8 mm to 21 mm in diameter. The operative blood loss in these patients was as follows: under 30 ml in 11 (10 children and 1 adult), under 50 ml in 8 (7 children and 1 adult), under 80 ml in 6 (4 adults and 2 children), and in 4 adults the blood loss ranged from 100 ml to 110 ml. There has been no instance of postoperative complication.

I thank Professor G. B. Ong, Head of the Department of Surgery, for advice and encouragement. The figures were drawn by Dr. M. Grant.
