ABSTRACT We have studied the sputum/serum protein concentration ratios from 23 patients with bronchitis both in the stable clinical state and during acute chest infections. During the stable state there was a significant negative correlation (2 r<0.005) between the ratio and protein size. The ratios of IgG, IgA, Cα, and alpha1-antichymotrypsin were significantly displaced from this relation suggesting local production in the lung. IgM was found in all samples and alpha2-macroglobulin in 55% of non-infected samples which may be the result of local production rather than transudation from serum, because of their larger size. During acute chest infections the albumin content of sputum rose from a mean sputum/serum ratio of 0.83 (SE±0.08)×10⁻² to 13.77 (SE±3.21)×10⁻² suggesting increased transudation from the blood. In the presence of increased transudation, local production of protein appears to be less significant.

The role of immunoglobulins and proteolytic enzyme inhibitors in protecting the lung from damage is far from clear. In particular there have been conflicting reports concerning the presence of these proteins within the bronchial secretions and whether they are locally produced in the lung.

There are five possible ways in which a protein may enter the bronchial secretions (fig 1). Mechanisms one and two show the production of proteins unique to the bronchial secretions by epithelial cells and submucous glands respectively.

These proteins would be found in the bronchial secretions but not in the serum; an example is the low molecular weight bronchial inhibitor of elastase (Tegner, 1978). Mechanisms three, four, and five relate to proteins also found in serum. These proteins may passively diffuse from serum (3), become structurally altered within the secretion exemplified by the addition of secretory piece to IgA (4), or be present as the result of passive diffusion together with local production by plasma cells or macrophages (5). Mechanisms 4 and 5 would result in higher concentrations of the protein in the bronchial secretion than could be explained by passive diffusion alone.

Burnett et al (1976) studied the diffusion of plasma proteins into amniotic fluid and showed that the protein concentrations were inversely related to their molecular sizes (fig 2). Protein A has a fluid to serum ratio greater than albumin and thus by convention shows evidence of local production or retention. Proteins B and C have ratios similar to or less than albumin. They are larger molecules, however, and their ratios are higher than would be expected for their size. This also suggests local production or retention.

The present study was designed to clarify the origin of plasma proteins in sputum by measuring their sputum to serum ratios and taking into
account their molecular sizes. We wished to determine whether any proteins were present in greater concentrations than would be expected by simple diffusion from serum thereby suggesting local retention or production.

Methods

Twenty-three patients with chronic bronchitis (MRC, 1965) aged 48–75 were studied. Sputum was collected over a four-hour period and a 10 ml sample of blood was taken during this time. The sputum was separated into sol and gel phase (the latter being discarded) by ultracentrifugation (100 000 g) for 90 minutes. The blood was allowed to clot, was centrifuged, and the serum was removed. Samples of serum and sol phase of sputum were stored at −20°C until analysed.

Three of the patients were studied during an acute chest infection, but the remainder were in a stable clinical state (at least two weeks after an infection).

Protein Measurements

Twelve proteins were measured in each sputum and serum sample (albumin, orosomucoid, transferrin, ceruloplasmin, haptoglobin, α1-antitrypsin (α1-AT), α1-antichymotrypsin (α1-ACh), α2-macroglobulin (α2-M), C3, IgA, IgG, and IgM). The immunoglobulins were measured by radial immunodiffusion (Mancini et al, 1965) and the remaining proteins by rocket immunoelectrophoresis (Laurell, 1966). All results were expressed as a percentage of a pooled reference serum (Immunodiagnostic Research Laboratory, Department of Immunology, University of Birmingham). The sputum to serum ratio was then calculated for each protein in each sample. Albumin was taken as the reference protein and the sputum/serum ratio for each protein was divided by the albumin result. This gave a value for albumin of 1 in each sample, and the remaining protein ratios were corrected for albumin.

Stokes Radii

The Stokes radii for most proteins were taken from Burnett et al (1976). Albumin, haptoglobin, α2-M, and IgM were taken from Felgenhauer (1971, 1974). The relation between sputum/serum protein ratios and Stokes radii was determined using the least squares method for linear regression for five proteins. Albumin, orosomucoid, transferrin, ceruloplasmin, and haptoglobin were chosen because they have a range of Stokes radius from 3–45–5.0 nm and have not been metabolically implicated in lung disease. Their presence in the sputum was assumed to be the result of passive diffusion alone.

The regression line was used to estimate the expected sputum/serum ratios of the other proteins for their Stokes radius by interpolation. The expected value was then compared to the observed value using the standard error of difference of means.

Results

All 12 proteins were found in each specimen except α2-M which was undetectable (<200 μg/l) in nine of the non-infected patients. Its ratio in these patients was therefore taken as zero.

The sputum/serum ratios of all the proteins
corrected for albumin are summarised in Table 1 for the non-infected patients (divided into smokers and non-smokers) and for the patients with active chest infection. At the bottom of the table is the actual albumin sputum/serum ratio (multiplied by 10² for convenience). In the non-infected patients this ranged from 0.45 to 1.37 but was much higher in the three patients with infection as shown in Fig 5 (7.53, 15.29, and 18.50). No significant difference was found between the smokers and non-smokers for the sputum/serum ratio of any protein.

**Relation to Stokes Radius**

**Non-infected patients**

There is a significant inverse relation between the corrected sputum/serum ratios and Stokes radius for the five proteins mentioned earlier. The relation can be expressed as: sputum/serum ratio = 1.55 - 0.179 × Stokes radius (SE = 0.36; r = -0.29; t = 2.999; 2p < 0.005) (Fig 3).

There are several proteins whose sputum/serum ratios lie outside this relation and some of them are significantly displaced (a1-ACh p < 0.001; IgG, p < 0.001; IgA, p < 0.001; IgM, p < 0.001; and C₃, p < 0.005).

**Infected patients**

The inverse relation was maintained in the three patients who had active chest infection. Figure 4 shows, however, that most other proteins lie within this relation. Only IgA (p < 0.001) remained significantly displaced. The relation was: sputum/serum ratio = 2.10 - 0.356 × Stokes radius (SE = 0.28; r = -0.62; t = 2.849; 2p < 0.02).

The intercept is lower than in the non-infected patients. In the presence of inflammation larger proteins would be expected to leak into the secretions raising the intercept. Thus the finding of
α₂-M and IgM, which should be absent according to this relation, may merely reflect the small number of infected patients rather than local production.

Despite the fact that IgA is still present in greater concentrations than can be explained by simple diffusion it should be noted that its sputum/serum ratio corrected for albumin (1.80±2.46) was lower than in the non-infected patients (17.99±2.46). Figure 5 shows the sputum/serum ratios of albumin for smokers, non-smokers, and the infected patients, together with the IgA ratio corrected for albumin. The three patients with infection not only had the highest sputum/serum ratios but also the lowest IgA ratios corrected for albumin (range, non-infected=4.55–38.46; infected values=1.15, 1.94, and 2.31).

**Fig 5** Sputum to serum albumin ratio is given for smokers, non-smokers, and infected patients on left. IgA sputum/serum ratio corrected for albumin is shown in same groups on right.

**Discussion**

Bronchial secretions play an important part in protecting the epithelium of the respiratory tract, trapping inhaled particles, and humidifying the air. There are also several soluble proteins within the secretions that may perform a protective function.

Probably most of the soluble protein is derived from serum by passive diffusion, but several workers (Ryley and Brogan, 1973; Soutar, 1977; Warr et al, 1977) have noted that some proteins, particularly IgA, are present in higher quantities suggesting either local production or active transport into the secretions.

The situation with other proteins is less clear. Warr et al (1977) and Reynolds and Newball (1974) found relatively high concentrations of IgG in the secretions of smokers suggesting local production whereas Masson et al (1965) and Keimowitz (1964) found no evidence of local production. Tegner (1978) found that the proteolytic enzyme inhibitors α₁-AT, α₂-M, and α₁-ACh were present in bronchial secretions, but there was no evidence of local production. Ryley and Brogan (1973), however, presented evidence suggesting that α₁-ACh was locally produced in patients with bronchitis, although their methods were less accurate. These authors studied sputum, which is a mixture of bronchial secretions variably contaminated with saliva and a small amount of nasopharyngeal secretions, but they emphasised that this would cause dilution of samples rather than alteration of their protein profile. The dilutional effect is overcome by studying protein ratios rather than absolute concentrations, using albumin as a reference. Proteins with secretion/serum ratio less than albumin are said to be present by simple diffusion whereas those whose ratio is greater than albumin are thought to be present partly as a result of local production.

Secretion/serum ratios are also dependent upon protein molecule size (Burnett et al, 1976). This was recognised by Ryley and Brogan (1973). They found the IgG/albumin ratio was the same in sputum as serum, but suggested it should have been lower because IgG is larger than albumin, although they were unable to show this effect clearly.

The relation between sputum/serum concentration ratios and Stokes radius was established from data on five proteins chosen because of their differing sizes and because they have not been metabolically implicated in lung disease. An inverse relation was found suggesting that these five proteins were entering sputum by simple diffusion. In the non-infected patients four proteins had sputum/serum ratios significantly higher than predicted from this relation: IgA, IgG, C₃, and α₁-ACh. Alpha₂-M was found in 11 patients and IgM in all patients and because of their size one would predict that none should be present in sputum unless they were produced locally. However, caution must be expressed concerning α₂-M since its displacement is only minimal from an extrapolated line.

The immunoglobulins are probably synthesised by plasma cells within the lung, although IgA containing cells predominate (Martinez-Tello et al, 1968). The bronchial tree also contains many macrophages that are probably the source of C₃ production (Ruddy et al, 1972).

The protease inhibitors are of interest because of the association between α₁-AT deficiency and
emphysema (Eriksson, 1978). We have found evidence suggesting that $\alpha_2$-M and $\alpha_1$-ACh are locally produced or secreted into the bronchial fluids. Lung fibroblasts have been shown to manufacture $\alpha_2$-M in vitro (Kaighn and Prince, 1971) but information on $\alpha_1$-ACh is lacking. This enzyme inhibits cationic proteolytic enzymes from granulocytes by the formation of complexes (Ohlsson and Åkesson, 1976) and therefore may play an important part in protecting the lung from damage by these proteases. Whether $\alpha_1$-ACh is locally produced in the lung is not certain. Burnett (1975) found several samples of amniotic fluid had a higher fluid/serum ratio of $\alpha_1$-ACh than would be expected by diffusion. This may be explained by the presence of protein complexes which may alter the antigenic properties of $\alpha_1$-ACh resulting in its over-estimation and a broadened precipitation peak on two-dimensional electrophoresis. Ryley and Brogan (1973) measured $\alpha_1$-ACh using two-dimensional electrophoresis and commented that the precipitation peak was broadened compared to serum. We measured $\alpha_1$-ACh by radial immunodiffusion but have subsequently reviewed our samples using two-dimensional electrophoresis and found similar broadening of the $\alpha_1$-ACh precipitation peak to a variable degree (fig 6). This may, at least in part, explain the high sputum/serum ratios in our patients and merits further study.

There are several differences between the results in the non-infected and infected patients. The sputum/serum albumin ratio was much higher in the infected patients. Caution must be expressed in the interpretation of this finding because of small numbers and uncertainty about sample dilution by saliva. It is consistent, however, with increased protein transudation from serum due to bronchial inflammation.

The ratios of $\alpha_1$-ACh, IgG, and $C_3$ were not different from their predicted values in the infected patients and the IgA (fig 5) and IgM ratios were lower in relation to albumin. These findings are probably the result of increased protein transudation. Local production of protein is likely to be small and highlighted by the relative absence of protein from other sources (serum). When inflammation occurs, protein transudation would increase exceeding local protein production, thus decreasing the relative contribution from local production. The sputum/serum ratios would be reduced to values closer to those expected by diffusion from the serum. This is more likely to account for the low IgA ratios in infection than a reduction in local synthesis as suggested by Soutar (1977). A further study of the relative quantities of IgA and secretory IgA in patients with and without active chest infection would be necessary to clarify this observation.

This work was supported by grants from the Medical Research Council, Boehringer Ingelheim, and the Rowbotham Bequest. We thank Professors R Hoffenberg and J M Bishop for their encouragement and advice and Mrs W Davis for her typing.
