Spontaneous dissection of the oesophagus

G N MORRITT AND P R WALBAUM

From the Thoracic Surgical Unit, City Hospital, Edinburgh

ABSTRACT Spontaneous rupture of the oesophagus is a well-known entity. Partial or intramural rupture of the oesophagus has been described but is not so well known, and the purpose of this paper is to draw attention to this condition. The clinical presentation, radiological appearances, and treatment of two such cases are described.

Spontaneous perforation of the oesophagus was first described by Boerhaave in 1724. When Barrett reported three cases of spontaneous rupture of the oesophagus and reviewed the published cases in 1946 there was a total of 50 cases. The next year Barrett reported the first successful repair of a spontaneous oesophageal perforation. In a more recent review there was a total of 300 reported cases. Usually the rupture is complete. However, it is possible for the oesophageal rupture to be intramural—that is, rupture of the mucosa alone leaving the muscle wall intact, with dissection of the mucosa off the muscle layer. This is a rare condition and has been described after instrumentation of the oesophagus. A few cases of spontaneous intramural dissection of the oesophagus have been described. We describe a further two cases.

Case reports

CASE 1
A 72-year-old woman felt nauseated after a large meal and shortly afterwards vomited profusely (“as if I was bringing up all the food I had eaten in the last two days”) and experienced severe pain in the epigastrium radiating along the right costal margin which doubled her up and caught her breath. The severe pain lasted only a few minutes but she continued to have aching pain and retrosternal pain on swallowing. Twenty minutes later she vomited again and on this occasion there was blood in the vomit.

Over the next two days she felt very unwell but the pain on swallowing eased off and she was able to take liquids by mouth.

She was admitted to hospital two days after the event. Clinical examination revealed no abnormality. In particular there was no surgical emphysema and no epigastric tenderness. A chest radiograph was normal. Barium meal showed a small sliding hiatus hernia and filling defects with an irregular posterior margin, the appearances being consistent with partial rupture. Oesophagoscopy was performed with a rigid instrument. At 28 cm from the upper alveolus there was a bulge in the posterior wall of the oesophagus and the overlying mucosa was purplish in colour. The oesophagoscope was not passed beyond this point. The appearances were those of an extensive submucosal haematoma probably the result of rupture of the oesophageal mucosa. No tear was seen. She was treated conservatively with intravenous fluids and no oral intake for four days. Her symptoms improved. Oral fluids introduced after this were well tolerated. She was discharged home in good health and swallowing normally on the fifteenth day after admission.

CASE 2
A 68-year-old widowed pensioner was admitted to hospital. She had no previous history of symptoms related to her upper gastrointestinal tract and had been in normal health except for episodes of chest discomfort which were diagnosed as angina. At 1800 on the day of admission she had her usual tea of scrambled eggs and toast. About an hour later she experienced retrosternal discomfort which was followed by repeated swallowing and belching of air. The retrosternal discomfort developed into an acute pain which was made worse by swallowing. She was seen by her family doctor 45 minutes later, by which time she was still in intense pain and was cold and sweaty. A diagnosis of possible myocardial infarction was made and
Spontaneous dissection of the oesophagus

she was transferred to the local hospital's coronary care unit.

The next morning she regurgitated 10 ml of blood-stained saliva. She continued to complain of pain on swallowing. Serial electrocardiograms and cardiac enzymes showed no abnormality. She was kept under observation and given a normal diet. During the next five days she continued to experience dysphagia at mid-sternal level. On the sixth day after admission, a barium swallow examination was repeated and showed that the contrast medium entered and collected within the wall of the oesophagus over a 7 cm length, approximately midway between the carina and the diaphragm. There was no free perforation.

On reviewing the films of the first barium examination intraluminal filling defects were seen—these probably represented blood clots that were present at that time and which had since cleared. In view of these findings a diagnosis of incomplete or intramural rupture of the oesophagus was made and she was treated conservatively with intravenous fluids and oral intake was withheld. Her dysphagia improved over the next days. Barium examination was repeated eight days later and was completely normal (fig 2). A normal diet was resumed and she was discharged from hospital in good health.

Fig 1 Barium swallow study six days after partial rupture showing contrast medium within the wall of the oesophagus.

Discussion

In 1968 the first case report of a spontaneous intramural oesophageal perforation was made from Capetown by Marks and Keats. Over the subsequent two years there were further case reports. These cases illustrate the essential features of the condition. The patients did not have any pre-existing oesophageal disease. They presented with discomfort in the retrosternal region which was not usually related to a meal. The discomfort occurred hours later, followed by severe pain radiating to the epigastrium or the back, associated with retching and occasional
small amounts of red blood in the vomit. This has
to be differentiated from the Mallory Weiss Syn-
drome,12 where haematemesis is the main feature,
and from spontaneous complete transmural oeso-
phageal perforation which usually occurs after a
large meal followed by violent vomiting. Clinical
examination reveals a low grade fever and absence
of surgical emphysema in the neck. The chest
radiograph is usually normal. The radiological
changes produced by intramural dissection of the
oesophagus may show a striking similarity to
the typical findings in dissecting aneurysm of the
aorta. The true and false oesophageal lumina may
be demonstrated, separated by a mucosal stripe
resembling the appearance of the intima in aortic
dissection.11 There may be longitudinal filling de-
fects which represent blood clot in the oesophageal
wall. Subsequent films will show contrast medium
remaining in the oesophageal wall (fig 1). In ad-
inistration there is absence of normal peristalsis over
the affected area. These patients respond to con-
servative treatment—that is, antibiotics, witholding
oral fluids, bed rest, and intravenous fluids. A
repeat barium swallow usually shows a normal con-
tour to the oesophagus some days later.

In our first case vomiting occurred one hour
after a large meal and was followed by severe
epigastric and retrosternal pain associated with
dysphagia, which persisted for several days. Oeso-
phagoscopy and barium swallow were diagnostic.
In our second case there was no vomiting. Retro-
sternal pain occurred an hour after the last meal.
In both cases there was a history of regurgitation
of a small amount of red blood hours after the
onset. The first case was correctly diagnosed. In
the second case a diagnosis of myocardial infarc-
tion was made, despite the absence of supporting
ECG and enzyme evidence and the presence of
dysphagia and haematemesis. Spontaneous oeso-
phageal perforation may be either complete (trans-
mural) or incomplete (intramural/dissection).
Vomiting is usually a prominent feature of the
former variety. Constant retrosternal pain with
severe dysphagia for liquids without clinical and
radiological abnormalities (on the chest radiog-
raph) are the hallmarks of the latter variety. It
is important to make the distinction between the
two types of oesophageal perforation because the
treatment in the first is operative whereas in
the latter it is conservative.
