Effect of oral salbutamol and slow-release aminophylline on exercise tolerance in chronic bronchitis

AG LEITCH, A MORGAN, DA ELLIS, G BELL, C HASLETT, GJR McHARDY

From the Department of Respiratory Medicine, University of Edinburgh, City Hospital, Edinburgh

ABSTRACT  In a double-blind placebo-controlled trial in 24 patients fulfilling the MRC criteria for chronic bronchitis, oral salbutamol 4 mg and slow-release aminophylline (Phyllocontin) 450 mg produced similar and significant (p < 0.05) mean increases in forced expiratory volume in one second (FEV₁). A significantly greater increase in mean FEV₁ and forced vital capacity (FVC) was seen when both drugs were given although there was no statistical evidence of synergistic interaction. Salbutamol significantly increased the mean distance walked in 12 minutes (12MD) (p < 0.02) by 56 metres and a similar increase of 54 metres (p < 0.001) was seen after Phyllocontin. With both drugs in combination mean 12MD increased by 51 metres (p < 0.02 cf placebo), a change not significantly different from that observed with either drug alone. Oral salbutamol and Phyllocontin improve exercise tolerance in chronic bronchitis. The significantly greater changes in FEV₁ and FVC resulting from simultaneous administration of the two drugs are not associated with further improvement in exercise tolerance.

We have previously shown the value of the 12-minute walking distance (12MD) in assessing exercise tolerance in dyspnoeic patients and have used this test to assess the effect of aerosol bronchodilators on exercise tolerance in patients with chronic bronchitis.²

There are good theoretical reasons for anticipating a beneficial interaction between theophyllines and β-adrenergic agents in airways obstruction,³ and such an interaction has been demonstrated in asthmatic patients.⁴ We have therefore compared the effects of a β-adrenergic agent, salbutamol, and a theophylline, Phyllocontin (slow-release aminophylline), given singly and in combination by the oral route, on FEV₁, FVC, and 12MD in a double-blind controlled study to see if a similar interaction occurs in chronic bronchitic patients.

Patients and methods

We studied 24 patients who fulfilled the Medical Research Council criteria for chronic bronchitis (table 1). All had been or were heavy cigarette smokers, none had peripheral blood eosinophilia,

and patients with positive skin tests to common allergens were excluded. Patients who had angina, intermittent claudication or a locomotor disorder were also excluded. Bronchodilator agents were withheld for 12 hours before the studies. We measured FEV₁ and FVC on a low resistance spirometer,⁶ taking the best of three readings,⁷ and we also measured the 12MD.¹

We studied the patients on five consecutive days. On the first day we measured 12MD on two occasions to accustom the patient to the test and to exclude early training effects.¹ The Latin-Square design of the trial allowed for within-study training effects. On each of the other four days the patients received, on a double-blind basis, one of the four following treatments, according to a Latin-Square

design: (a) placebo + placebo; (b) Phyllocontin 450 mg + placebo; (c) placebo + salbutamol 4 mg; (d) salbutamol 4 mg + Phyllocontin 450 mg.

We measured FEV₁, FVC, and 12MD before and three hours after each treatment. We calculated analyses of variance that used the Latin-Square design of the trial thus enabling unbiased comparisons between treatments to be made. These analyses are briefly summarised in Table 2 and the results of significance tests among the treatment means are indicated by asterisks.

We also calculated correlation coefficients for 12MD with FEV₁ and FVC.

Results

The results are summarised in Table 2. There were no significant differences at the 5% level between the baseline values for FEV₁, FVC, and 12MD before each treatment.

For both FEV₁ and FVC the mean increase after treatment was greater after all active treatments than after placebo. For each comparison with the placebo the t statistic was significant except for change in FVC after Phyllocontin alone (Table 2). The mean increases in both FEV₁ and FVC after the combined active treatment were significantly greater than those seen after either single active treatment (p < 0.001). The mean changes in 12MD after all three active treatments were similar and significantly greater than that after placebo (p < 0.02), but the differences between the combined and single active treatments were not significant.

Of the measurements made before treatments with placebo 12MD correlated better with FVC (r = 0.5981) than with FEV₁ (r = 0.4723).

Discussion

The changes in FEV₁, FVC, and 12MD after drugs were recorded at a time when the serum levels and bronchodilator effects of both drugs were likely to have reached a maximum. The doses used were chosen on the basis of previous work showing maximum bronchodilatation at these doses without side-effects. With these standard doses we have demonstrated significant increases in FEV₁ and, for the first time, significant increases in 12MD in patients with chronic bronchitis after oral bronchodilator therapy with either salbutamol or Phyllocontin. Combination of the two active agents produced significantly greater increases in FEV₁ and FVC than with either agent alone. Nevertheless, this further bronchodilatation was not associated with any further improvement in 12MD.

We have now demonstrated similar improvements in 12MD after aerosol and oral bronchodilator therapy in patients with chronic bronchitis. In neither study do our results suggest a close correlation between changes in FEV₁ and 12MD. This could be related to poor physical fitness in our patients. This would restrict their ability to benefit maximally in terms of exercise tolerance from the acute improvements in airways obstruction produced by the bronchodilator medications. Such a hypothesis is open to testing in chronic bronchitic patients who have been trained.

We conclude that oral salbutamol and Phyllocontin in conventional dosage improve exercise tolerance in chronic bronchitis. Simultaneous administration of the drugs is not associated with any further improvement in exercise tolerance.

We are grateful to Messrs Allen and Hanburys and Messrs NAPP for providing active and placebo drugs, to Mrs MV Shotter for statistical advice, and to Mrs R Haldane for secretarial help.
