Changes in transcutaneous oxygen tension during exercise in pulmonary emphysema

JA HUGHES, BJ GRAY, DCS HUTCHISON

From the Chest Unit, King's College Hospital Medical School, London

ABSTRACT Continuous measurements of transcutaneous oxygen tension (tcPO₂) were made in 23 patients with radiological evidence of emphysema, at rest and during a maximal progressive exercise test. tcPO₂ during the final phase of exercise was compared with tcPO₂ at rest; the mean change (exercising minus resting value) in tcPO₂ (ΔtcPO₂) was -0.8 mm Hg (SD 10.5, range -18 to +25) (-0.1 kPa (SD 1.4, range -2.4 to +3.3)). ΔtcPO₂ was correlated with: resting arterial oxygen tension (Pao₂) (r = 0.606, p < 0.005); resting arterial carbon dioxide tension (PaCO₂) (r = -0.691, p < 0.001); FEV₁, % predicted (r = 0.688, p < 0.001); vital capacity % predicted (r = 0.543, p < 0.01); and transfer factor (TLco) % predicted (r = 0.604, p < 0.005). There was no significant difference between the ΔtcPO₂ of 10 patients who regularly produced sputum and of 13 patients with no sputum. ΔtcPO₂ appears to be more closely related to the severity of emphysema than to the presence or absence of chronic bronchitis. Pretreatment with fenoterol aerosol resulted in an increased work load in three out of 10 patients. Overall there was no change in ΔtcPO₂. In all except one patient there was a rise in tcPO₂ after the end of exercise. In the 11 patients whose tcPO₂ fell during exercise, tcPO₂ returned to the resting value within two minutes of the cessation of exercise; this was followed by a further rise beyond the resting value, and a single postexercise arterial sample is therefore a poor indicator of the response of Pao₂ to exercise. Measurement of tcPO₂ is of value in following rapid changes in Pao₂ during and after exercise and avoids the necessity for an indwelling arterial cannula.

Changes in arterial oxygen tension (Pao₂) during exercise in patients with chronic airflow obstruction were reported by Jones, who showed that patients with emphysema tended to develop further hypoxaemia during exercise whereas there was a rise in Pao₂ in patients who had a similar degree of airflow obstruction but no emphysema. There has subsequently been much discussion of the possible physiological mechanisms underlying these findings. We have therefore carried out a similar study of the exercise induced blood gas changes in patients with emphysema of a wide range of severity with and without chronic bronchitis.

Inhaled bronchodilator agents have been shown to produce appreciable improvement in vital capacity in emphysematous patients at rest, though the improvement in exercise capacity is relatively small.

In this study we have taken advantage of the opportunity to investigate the effects of the β₂ adrenergic agent fenoterol on exercise induced changes in blood gases.

During exercise Pao₂ is commonly monitored by intermittent direct sampling from an arterial cannula or indirectly on the basis of capillary samples from the warmed earlobe. Non-invasive monitoring techniques include the ear oximeter for the estimation of arterial oxygen saturation and the transcutaneous oxygen electrode, which we have used in this study.

The transcutaneous oxygen electrodes are applied directly to the skin surface and incorporates a thermostatically controlled heater designed to promote dilatation and arterialisation of the local capillary circulation. The method has been used predominantly in the intensive care of newborn infants, where it gives reliable results, and it has been shown to provide a good estimate of Pao₂ in adult patients. A close relationship between transcutaneous oxygen tension (tcPO₂) and Pao₂ has been
Changes in transcutaneous oxygen tension during exercise in pulmonary emphysema

shown in normal adults and in children with chronic lung disease, and a further objective of this study was to ascertain whether measurement of tcPO₂ is of value in the assessment of blood gas changes during exercise in adults with chronic airflow obstruction.

Methods

Twenty three men with radiological evidence of pulmonary emphysema were studied. The patients gave informed consent and the project was approved by the King's College Hospital ethical committee. Thirteen patients (group A) produced little or no sputum and 10 (group B) had produced sputum for sufficient time to satisfy the Medical Research Council criteria for simple chronic bronchitis.

STUDY 1

The patients rested for 30 minutes after arrival at the laboratory; the FEV₁, relaxed vital capacity (VC), and inspiratory capacity were then measured with a Bernstein spirometer. Transfer factor for carbon monoxide (TLCO) and transfer coefficient (Kco) were measured by the single breath method (PK Morgan transfer test). Total lung capacity (TLC) and residual volume (RV) were derived from the functional residual capacity (FRC), which was measured with a Collins 09001 whole body plethysmograph. Predicted values were obtained from tables prepared by Cotes.

Transcutaneous oxygen tension was measured by the polarographic method by means of a platinum electrode (Drägerwerk, Lübeck, West Germany) heated to 45°C and applied to the skin surface over the biceps muscle; the design of the electrode is similar to that described by Huch et al. The output of the electrode could be read digitally or displayed on a chart recorder. Details of the calibration procedure are given at the end of this section.

A progressive exercise test was performed on an electrically braked cycle ergometer. The tcPO₂ was monitored for at least one minute while the patient was seated at rest on the cycle ergometer, until a constant reading was obtained (tcPO₂: rest) and was monitored throughout the exercise study and for 30 minutes after the end of exercise. tcPO₂ was noted at the instant the patient stopped exercise (tcPO₂: end ex) and when it reached the highest value during the postexercise period (tcPO₂: post ex). The tcPO₂ values at these specific points were read from the digital meter.

During the first minute of exercise no additional work load was applied; thereafter the load was increased by 10 watts every minute until the maximum load was attained. The electrocardiogram was displayed throughout the procedure but no dysrhythmic or ischaemic episodes were observed. Ten patients included in study 1 received two puffs from a placebo aerosol 30 minutes before the start of exercise as a preliminary to study 2.

STUDY 2

Ten patients who had performed study 1 took part in a single blind study to compare the effects of fenoterol and placebo aerosols on tcPO₂ during exercise. In these patients the placebo aerosol was administered as part of study 1. Forty five minutes after the end of study 1, FEV₁, VC, and TLC were measured before and 30 minutes after two puffs (400 μg) from a fenoterol metered dose aerosol canister. The progressive exercise test was then repeated, tcPO₂ being monitored at rest and during exercise as in study 1. The electrode remained in place throughout both studies. The drift was never more than 5% in any study and in most it was substantially less; the measurements were therefore not corrected for drift.

CALIBRATION OF tcPO₂ ELECTRODE

Before each study the electrode was calibrated in vitro at two points, sodium sulphite solution (zero oxygen tension) and atmospheric air being used. The electrode was then attached to the patient and after an interval of not less than 30 minutes (by which time a steady tcPO₂ reading had been obtained) an arterial blood sample was taken by brachial or radial puncture. Arterial carbon dioxide tension (PaCO₂) and PaO₂ were measured immediately (Dow-Corning analyser, type 165). The gain control of the tcPO₂ system was then altered so that the output corresponded to the measured PaO₂; we have called this procedure in vivo calibration. At the end of the study, the in vitro calibration against atmospheric air was repeated and shown to correspond to the initial value, after allowance had been made for any alteration in gain control necessitated by the in vivo calibration procedure.

We have shown by simultaneous measurement of PaO₂ and tcPO₂ in 14 patients that this in vivo calibration procedure considerably improves the accuracy of tcPO₂ measurement. For 55 data points over the range 50–120 mm Hg we obtained the relationship

\[
tcPO₂ (\text{mm Hg}) = 0.98 \times PaO₂ + 1.61 \\
(95\% \text{ confidence limits } \pm 6.6 \text{ mm Hg}).
\]

An example of the close relationship between PaO₂ and tcPO₂ is shown in figure 1; during the postexercise rise in arterial PO₂ the response of the tcPO₂ electrode was complete within two minutes. The
above regression equation and the results illustrated in figure 1 were obtained with the Radiometer electrode rather than the Dräger electrode used for the main part of this study, but we and others\textsuperscript{15,16} have found that they have similar characteristics. Results similar to those shown in figure 1 have been obtained in a further five patients studied in this laboratory.\textsuperscript{17}

The significance of differences between groups was assessed by means of a paired or unpaired Student's $t$ test as appropriate.

**Results**

**STUDY 1**

The age and lung function indices of the patients in groups A (no sputum) and B (chronic bronchitis) are shown in table 1. Patients in group B were significantly older ($p < 0.02$) than those of group A. FEV\textsubscript{1}, VC, TLC\textsubscript{o}, and K\textsuperscript{o} (as percentages of predicted values) were all lower in group B than in group A, but in no instance were the differences significant at the 5% level. There was no significant difference between the groups in resting Pa\textsubscript{o} or Pa\textsubscript{CO\textsubscript{2}} (table 2).

The changes in tc\textsubscript{PO\textsubscript{2}} ($\Delta$tc\textsubscript{PO\textsubscript{2}}) are shown in table 2 and two examples of tc\textsubscript{PO\textsubscript{2}} tracings in figures 2 and 3. In group A tc\textsubscript{PO\textsubscript{2}} rose on average by 1.4 (SD 10.9) mm Hg by the end of the exercise; in group B it fell by 3.7 (9.3) mm Hg. In neither group A nor group B was $\Delta$tc\textsubscript{PO\textsubscript{2}} significantly different from zero and there was no significant difference between the groups.

With the exception of one patient in group A, all patients showed a rise in tc\textsubscript{PO\textsubscript{2}} after exercise (table 2). The mean difference between tc\textsubscript{PO\textsubscript{2}} at the end of the exercise and tc\textsubscript{PO\textsubscript{2}} at the peak of the postexercise rise was 18.8 mm Hg in group A and 19.7 mm Hg in group B; there was no significant difference between the two groups. The average interval between the end of the exercise and the maximum postexercise tc\textsubscript{PO\textsubscript{2}} was 4.2 minutes (range 3.6-6.5 minutes). Thirty minutes after the end of exercise the mean tc\textsubscript{PO\textsubscript{2}} was still significantly above the initial resting value. The change in tc\textsubscript{PO\textsubscript{2}} during exercise ($\Delta$tc\textsubscript{PO\textsubscript{2}}), defined as tc\textsubscript{PO\textsubscript{2}} end exercise minus tc\textsubscript{PO\textsubscript{2}} rest, was found to be significantly correlated with the arterial blood gas tensions and most lung function indices (table 3) when data from both groups were considered together. There was, however, no significant correlation between $\Delta$tc\textsubscript{PO\textsubscript{2}} and TLC.

**STUDY 2**

At rest the placebo aerosol had no significant effect ($p > 0.05$) on FEV\textsubscript{1}, or VC in the 10 patients studied. After administration of fenoterol the mean FEV\textsubscript{1} increased by 0.16 litres ($p < 0.02$) and the mean VC by 62.1 ($p < 0.01$). The mean tc\textsubscript{PO\textsubscript{2}} increased by 5.3 mm Hg ($p < 0.02$).

Overall there was no significant change in tc\textsubscript{PO\textsubscript{2}} during exercise either after placebo or after fenoterol (table 4). There was on average no significant difference between the placebo and fenoterol responses ($p > 0.05$). There was no significant difference ($p > 0.05$) in fenoterol

Significance of difference between groups A and B (unpaired t test)  NS  NS  NS  NS

Values for postexercise peak minus end exercise tcPO₂ significantly different from zero in both group A and group B.

*Paired t test.

Conversion: Traditional to SI units—Oxygen tension: 1 mm Hg = 0.133 kPa.

NS—not significantly different from zero (either group or both together).

Response between groups A and B, though the number of patients was small.

Three patients (A2, A3, and B3) achieved a greater work load after fenoterol; for the sake of comparison therefore tcPO₂ end ex for the fenoterol study was taken not at the point of the maximal load but for the load equal to the maximum load attained during the placebo exercise test.

No significant correlation (r = 0.403, p > 0.1) was observed between the change in VC after fenoterol and the effect of fenoterol on the tcPO₂ response to exercise (that is, ΔtcPO₂ fenoterol minus ΔtcPO₂ placebo).

Discussion

Conflicting results have been obtained concerning the changes in PaO₂ during exercise in patients with chronic airflow obstruction. In one of the early studies Jones investigated two groups of patients; the first (group A) had radiological evidence of emphysema or lung function values which strongly supported that diagnosis, and the second (group B) had severe airflow obstruction but no evidence of emphysema. There was a mean fall in PaO₂ of 11.6 mm Hg in group A, but in contrast there was a mean rise of 6 mm Hg in group B.
their "bronchitic" subjects, who had evidence of heart failure and polycythaemia. Ten of the "bronchitic" patients subsequently had a postmortem examination; eight were found to have severe emphysema, perhaps explaining in part why the findings are not in agreement with those of Jones.16

Emmanuel and Moreno,19 in a study of patients who had radiological evidence of emphysema, observed a rise in arterial oxygen saturation in those with milder disease but a fall in those with more severe disease. Minh et al20 selected patients with chronic airflow obstruction (without definite evidence on the presence or absence of emphysema) and showed that those patients in whom PaO2 fell with exercise had more severe impairment of lung function than did those in whom PaO2 rose or remained unchanged.

We selected patients who had definite radiological evidence of emphysema and have shown that in the milder cases there is a rise in PaO2 with exercise, whereas there is a fall in the more severely affected patients. We have not, however, studied patients similar to those in Jones’s group B, who had airflow obstruction without emphysema.1 Such patients are often described as bronchitic, but it is clear from our results that the presence of simple chronic bronchitis (persistent sputum production) makes no difference to the exercise induced changes in tcPO2 in emphysema. The commonly stated view that so-called bronchitic patients show a rise in PaO2 with exercise while "emphysematous" patients show a fall is an oversimplification of the true position.

The type of exercise may also be important in determining the blood gas changes, and this has seldom been taken into account. Cohn and Donoso21 showed that there was little change in PaO2 during steady state treadmill exercise, although there was an obvious fall during a step test, which is a more strenuous form of exercise similar to the progressive test used by us. Tests at maximal exercise capacity

Placebo v fenoterol (paired t test): rest, p < 0-025; end exercise (end ex), p < 0-005.

*The change in transcutaneous oxygen tension (ΔtcPO₂) for fenoterol refers to value obtained at same work load as placebo maximal load.
†Three subjects who performed more work after fenoterol.
NS—not significant at 5% level.

Conversion: Traditional to SI units—Oxygen tension: 1 mm Hg = 0-133 kPa.

would be expected to demonstrate changes in PaO₂ or tcPO₂ more readily than submaximal tests.

Early interest in the physiological reasons for the exercise induced changes in PaO₂ centred around the differing responses seen in the “emphysematous” and “chronic bronchitic” types of patient. Jones’ postulated that in the bronchitic patient the increase in PaO₂ was brought about by a rise in the ventilation of lung units with a low ventilation:perfusion (V/Q) ratio. It was subsequently confirmed by the multiple inert gas infusion technique that in such patients there is considerable blood flow to units with a very low V/Q ratio (0-03-0-01); arterial Po₂ would be sensitive to changes in the ventilation of such units.

In emphysema, however, the position is very different. There is substantial ventilation of units with a high V/Q ratio, but no evidence of the low V/Q units found in the group B patients. It could be argued that low V/Q units, or even a true shunt, could come into being with heavy exercise in emphysema; but it seems more likely that diffusion limitations will begin to play a part. In emphysema the destruction of the lung parenchyma brings about an enlargement in the terminal air spaces (and thus a longer diffusion path), a reduction in the surface area of the alveolar-capillary membrane, and a reduction in the pulmonary capillary volume. The last of these changes would lead to a reduction in the transit time of blood through the capillary and this effect would be greater with increase of pulmonary blood flow. If transit time is severely reduced, the oxygen tension of the pulmonary capillary blood will not have time to reach equilibrium with alveolar gas. It has been calculated that a fourfold reduction in diffusing capacity would be required to produce a significant fall in PaO₂ by this mechanism. The steady fall in tcPO₂ with increasing work load seen in most of our more severely affected patients appears to be consistent with the hypothesis that exercise induced hypoxaemia is at least partly due to diffusion limitation associated with a reduced transit time; an increase in the dispersion of transit times would further reduce PaO₂.

The onset of relative alveolar hypoventilation during exercise might also account in part for a reduction in PaO₂, but we were not able to measure PaCO₂ in this study. In previous studies, however, a rise in PaCO₂ during exercise occurred in relatively few emphysematous patients and hypoventilation is therefore not likely to be an important contributor to the fall in PaO₂.

Administration of bronchodilator aerosols to emphysematous patients has been shown to produce a moderate increase in 12 minute walking distance, although it may fail to improve maximal exercise tolerance during a progressive test on a cycle ergometer. In the present study only three of the 10 patients (table 4) achieved a greater work load after fenoterol than after placebo. The average resting tcPO₂ after fenoterol was 5-3 mm Hg greater than after placebo (p < 0-02) and 4-2 mm Hg greater than placebo after exercise (p < 0-005). Owing to unavoidable limitations on the study protocol, fenoterol was always administered after placebo, though the nature of the aerosols was not known to
the patients. The precise reasons for the observed increases in tcPO₂ after fenoterol are therefore not known but could include improved ventilation-perfusion relationships or an effect of the first post-exercise rise. Electrode drift is another possibility but this was never more than 5% over the whole study period. The fact remains that, despite the appreciable increase in VC, the results taken overall showed no difference between ΔtcPO₂ values after fenoterol and after placebo, although the two patients (B3 and B4) who had the greatest fall in tcPO₂ after placebo showed a much reduced fall after fenoterol. We have no evidence about the reproducibility of exercise induced changes in tcPO₂ and further work is required to determine whether large falls in tcPO₂ can consistently be modified by bronchodilator treatment.

Calibration of the transcutaneous PO₂ electrode using atmospheric air has proved satisfactory in newborn infants but is less precise in adults, presumably owing to unpredictable variations in the thickness and metabolism of the skin and the state of the local circulation. The “in vivo” calibration method used in the present study circumvents some of these sources of variation and an accurate estimate of PaO₂ can be obtained by this means. We have shown that a transcutaneous electrode can reflect the blood gas changes taking place during a single progressive exercise test with reasonable accuracy (fig 1). The performance of the electrode would be acceptable for clinical purposes.

At the end of the exercise period (figs 2 and 3) tcPO₂ underwent a rapid increase in all but one patient. To avoid arterial cannulation, the blood gas response to an exercise test is quite commonly assessed by means of a single arterial puncture after the end of the exercise, but our results show that if there is any delay in obtaining the blood sample the lowest PaO₂ value will almost certainly be missed and the test invalidated. A similar conclusion was reached by Ries et al, who measured PaO₂ via an indwelling cannula in some patients with chronic airflow obstruction; in most they observed a rapid rise in PaO₂ immediately after the end of exercise. The sudden reduction of metabolic demand and the resulting rise in central venous PO₂, coupled with persisting ventilatory stimulation, are factors which presumably contribute to the rapid postexercise increase in PaO₂.

Any changes in skin blood flow occurring during exercise could theoretically influence tcPO₂, but the close correspondence between tcPO₂ and PaO₂ observed in the type of patient illustrated in figure 1 suggests that this effect is not of great importance. The operating electrode temperature of 45°C presumably ensures maximal vasodilatation in the adjoining skin. This method seems preferable to derivation of PaO₂ from measurement of oxygen saturation by ear oximetry, as this would require simultaneous estimation of arterial pH and would have an unacceptable error at higher levels of oxygen saturation.

We conclude that the transcutaneous PO₂ electrode can provide a valid estimate of PO₂ during exercise in emphysematous patients. It seems likely that this would hold good in normal subjects and patients with other disorders, provided that no undue vasoconstriction took place.

We owe grateful thanks to the medical staff of WB Pharmaceuticals Ltd for financial support, to Eleanor Allan for statistical advice, to the technical staff of the chest unit, and to Mary Ewing and Catherine Barton for secretarial assistance.
