Angiotensin converting enzyme and endotoxin induced lung damage in the mouse

WOCM COOKSON, MS WISEMAN, DJ SHALE
From the Osler Chest Unit, Churchill Hospital, Oxford

ABSTRACT Acute pulmonary oedema can be induced by intraperitoneal injection of Escherichia coli endotoxin in the mouse. A fall in serum angiotensin converting enzyme activity is found in mice given endotoxin and in patients with septic adult respiratory distress syndrome, and has been proposed as an indicator of lung microvascular injury. Protein concentration and angiotensin converting enzyme activity in serum, lung, and bronchoalveolar lavage fluid were determined in male mice up to eight hours after injection of endotoxin. By six hours the serum protein concentration had increased and the bronchoalveolar lavage fluid protein concentration had fallen, suggesting fluid shift into the lung. Angiotensin converting enzyme activity fell in serum and lung but increased in bronchoalveolar lavage fluid. As these changes in enzyme activity were not paralleled by changes in protein concentration they are unlikely to be a result of fluid shift or protein leak, and may indicate an active role of the enzyme in the response to sepsis.

Angiotensin converting enzyme is a glycoprotein with various biological activities. It catalyses the conversion of angiotensin I to the vasopressor octapeptide angiotensin II and mediates the destruction of bradykinin.

Angiotensin converting enzyme is concentrated on the luminal surface of pulmonary endothelial cells and its serum activity has been shown to alter in chronic and in acute pulmonary disease. A fall has been found in patients with the adult respiratory distress syndrome and in mice with endotoxin induced pulmonary oedema. Because of these findings it has been suggested that serum angiotensin converting enzyme be used as a clinical indicator of the state of the pulmonary endothelium and pulmonary circulation in adult respiratory distress syndrome. Previous studies have not provided evidence of microvascular injury other than a fall in serum angiotensin converting enzyme activity, which may, however, increase in other types of experimental acute pulmonary insult. Little attention has been paid to any possible physiological role of the enzyme in these conditions.

This study aimed to define the distribution of angiotensin converting enzyme activity after pulmonary damage induced in the mouse by Escherichia coli endotoxin. Protein concentrations in lung, bronchoalveolar lavage fluid, and serum were used as indicators of fluid shift and capillary permeability and were compared with changes in the enzyme activity in these compartments.

Methods

The experiment was carried out on 48 male mice (Parkes strain, Medical Research Council) of mean (SD) body weight 41.6 (5.5) g. Ten control animals were given 2.5 ml/kg normal saline intraperitoneally. The remainder were given E coli endotoxin (serotype O111:B4, Sigma) 0.5 mg/kg intraperitoneally and were studied in groups of nine or 10 two, four, six, and eight hours after injection. There was no difference in mean body weight between any of the groups.

Specimens were obtained under pentobarbitone anaesthesia (May and Baker, 120 mg/kg intraperitoneally). The abdomen was opened and 1 ml of blood was taken from the inferior vena cava and allowed to clot on ice. Three millilitres of cold bicarbonate buffered normal saline (pH 7.4) were then injected into this vessel to clear the pulmonary circulation. The clotted blood was centrifuged at 500 g for 15 minutes and the serum decanted and stored at −15°C.
Angiotensin converting enzyme and endotoxin induced lung damage in the mouse

Fig 1 Changes in serum angiotensin converting enzyme (ACE) activity and protein concentration after administration of endotoxin to mice. Results are mean values with standard errors shown by bars.

Fig 2 Changes in bronchoalveolar lavage fluid angiotensin converting enzyme (ACE) activity and protein concentration after administration of endotoxin to mice. Results are mean values with standard errors shown by bars.

The trachea was exposed and the lungs were lavaged for 30 seconds with 2 ml of bicarbonate buffered saline. The volume of fluid recovered from the lavage was recorded. The lungs were then removed and blotted dry before storage at −15°C.

The lungs were allowed to thaw and their wet weights were recorded. Each pair of lungs was then minced with scissors and a weighed portion of each was heated at 60°C until a constant weight was obtained. The water content of the lungs was calculated from the loss of weight.

A 100 mg sample of each pair of freshly minced lungs was homogenised in 2 ml of cold phosphate buffer (0.1 mol/l K₂HPO₄; 0.3 mol/l NaCl, pH 8.3) with a ground glass tissue grinder. Each homogenate was centrifuged at 500 g for 30 minutes at 4°C and the supernatants were taken for angiotensin converting enzyme and protein estimations. The protein concentration was determined in lavage fluid, serum and lung homogenates by a colorimetric assay (Biorad Ltd, UK) with bovine serum albumin as a standard. Angiotensin converting enzyme activity was determined spectrofluorometrically with hippuryl-L-histidyl-L-leucine as the substrate (CBC Ltd) by the method of Friedland and Silverstein.

Statistical analysis of the results was carried out with Student's t tests.

Results

Serum angiotensin converting enzyme was significantly lower than control values in the mice.
studied 6 hours after injection of endotoxin (p = 0.030) (fig 1). Values were not different from those of controls by 8 hours. Serum protein concentrations were higher than control values in the mice studied 6 hours after injection (p = 0.003) but not different from control concentrations by 8 hours (fig 1).

The angiotensin converting enzyme activity in the bronchoalveolar lavage fluid was raised by two hours (p = 0.035) and remained raised at 4 (p = 0.001) and at 6 hours (p = 0.011) before returning to normal by 8 hours (fig 2). The lavage protein levels had fallen by 2 hours after injection (p < 0.001) and remained low at 4 (p = 0.002) and at 6 hours (p = 0.003), before reverting to normal by 8 hours (fig 2). The volumes of fluid recovered from the lavage procedure were increased at 6 hours after injection (p = 0.018) (table 1), but the changes in enzyme activity and lavage protein concentration remained significant when the volume of lavage fluid recovered was taken into account.

The total lung angiotensin converting enzyme activity fell by 4 hours (p = 0.036) and remained low at 6 hours (p = 0.015) before returning towards control values by 8 hours after injection (table 2). Neither the wet nor the dry lung weights altered significantly (table 1). There was, however, a trend for the wet weights to increase up to 6 hours after injection, and small increases in lung water content may have been swamped by lavage fluid. The increase in the volume of fluid recovered from lung lavage (table 1) 6 hours after injection was consistent with a fluid leak into the alveolar space. The total lung protein and the protein concentration per mg of dry lung did not alter (table 2).

**Discussion**

*E coli* endotoxin causes pulmonary oedema in laboratory animals by inducing capillary leakage of fluid. Any fluid flux may have effects on three pulmonary compartments: the intravascular, the interstitial, and the alveolar. In this study only two compartments, the intravascular and the alveolar, have been examined. But alveolar fluid may be taken to represent interstitial fluid, albeit with some modification by alveolar epithelium.

The increase in serum protein concentrations and the decrease in lavage protein concentrations found after endotoxin administration in this study are likely to be due to a protein poor fluid shift into the interstitial and alveolar spaces of the lung, although some fluid loss into other sites is probable. This is consistent with an early fluid shift into the lung found after endotoxin shock in the sheep, when the interstitial compartment of the lung has been studied by cannulation of lymphatics. We have not studied the later phase of the reaction to sepsis, when protein shift may exceed fluid shift.

The changes validate the use of this mouse model of septic pulmonary oedema, which is attractive because of its simplicity and its low cost. Histological confirmation of pulmonary changes is, however, desirable before the model can be fully accepted.

This study confirmed the previously reported reduction in serum angiotensin converting enzyme activity occurring in the first six hours after endotoxin injection. The effect is transient, with values returning to normal by 8 hours. As serum angiotensin converting enzyme increases after acute toxic pulmonary injury, this fall may indicate an adaptive response rather than, as has been suggested, a result of endothelial injury.

Estimations of enzyme in lavage fluid showed an unexpected increase, despite a fall in the total lung angiotensin converting enzyme activity. These results are unlikely to be due to a passive leak of the
enzyme into the lavage fluid as the molecular weight of angiotensin converting enzyme (136,000 daltons) is greater than that of albumin (65,000 daltons), which is the major component of protein measured by this assay system; and capillary leakage after this type of endothelial damage remains selective. The enzyme activity found in the lavage fluid might also result from angiotensin converting enzyme like activity in inflammatory leucocytes. In a different set of experiments we have shown that angiotensin converting enzyme activity after centrifugation of lavage fluid remains in the supernatant, and is minimal in resuspensions of the cellular precipitate (unpublished observations). The changes therefore suggest an active release, manufacture, or transport of the enzyme into or in the lung interstitium. The fall in total activity of the enzyme in the lung is consistent with depletion of stored enzyme and subsequent synthesis.

The reasons for the partitioning of angiotensin converting enzyme activity between the alveolar space and the circulation are unknown. This enzyme is a highly active biological substance with an important role in the production of angiotensin II. It may be presumed to play a part in circulatory volume and blood pressure homeostasis after septic insult, but this does not explain its appearance in alveolar lavage fluid. Possibly it is a part of a local response to fluid shift. It is a potent inhibitor of bradykinin activity, and angiotensin converting enzyme like activity due to cathepsin G may be found in neutrophils. The enzyme might therefore be expected to play some part, as yet undefined, in the inflammatory response.

Although serum angiotensin converting enzyme activity may rise or fall in various types of pulmonary disease the physiological bases for these changes are not known. The pulmonary concentration of the enzyme seems as important as the concentration of the circulating enzyme in the conversion of angiotensin I in the intact animal. Once in the serum, the enzyme is desialated and destroyed by the liver. Serum angiotensin converting enzyme activity may be the residue of an enzyme whose function is located elsewhere, as is the case with serum transaminases; alternatively it may represent partially deactivated enzyme, although the serum enzyme and the pulmonary enzyme do not seem to be different. Additionally, the serum activity is a balance between the rate of removal from the serum and the rate of release from the lung, both of which processes may be affected by sepsis.

This study has shown an as yet unexplained increase in angiotensin converting enzyme activity in the alveolar space after endotoxin administration that is not a result of simple protein diffusion or fluid shift. It seems likely that this enzyme acts as more than a passive marker of endothelial damage within the pulmonary circulation.
