pleurodesis
the (August considered with B. the association of asthma drugs in general with deaths from asthma tends to disappear, whereas the findings for fenoterol remain firm (a similar pattern occurred in the Saskatchewan study), 7). The table shows that control group A provides an adequate match for asthma severity, whereas some confounding exists in the unadjusted results for control group B. We drew this conclusion in the published study. Dr Lanes and his coworkers have simply repeated our analysis but misrepresented our conclusions. When the hazards of fenoterol are being considered it is important that all of the evidence should be considered. There is now a wealth of epidemiological, experimental, and clinical evidence that fenoterol is more hazardous than other commonly used β-agonists. 2 The peak New Zealand morbidity and epidemic started when fenoterol was introduced in 1976, and continued until our first study was published in 1989; the death rate then fell by one half, and is now similar to that in other countries. It is important to search for alternative explanations, but the evidence increasingly indicates that confounding by severity is not a plausible explanation, and that the association between fenoterol and deaths from asthma is likely to be causal.

Pleural abrasion: a new method of pleurodesis?

Pleural abrasion, as a means of pleurodesing the lung, is not a new technique, as implied by the name of Mr UU Nkere and others (August 1991;46:596-8). We and most thoracic surgeons in Australia have been performing transaxillary thoracotomies, apical bullae stapling, and bullae pleurodesis for at least 20 years. At the Prince Charles Hospital—a cardiothoracic hospital serving Queensland—in the period January 1985-December 1990, 320 patients were operated on in our thoracic surgical service for spontaneous pneumothorax. The mean age was 28 years and M:F ratio 1:1.4.1

Surgery was performed via the following surgical approaches: transaxillary thoracotomy (TAT) 244 patients, bilateral TAT 12 patients, and anterior thoracotomy 52 patients, anterior thoracotomy 6 patients, postero-lateral thoracotomy 6 patients. Pleurodesis was achieved thus: pleural abrasion 185 patients, talc with or without abrasion 42 patients, pleurotomy 84 patients, talc with or without pleurotomy 4 patients, other or unknown 5 patients. The mean postoperative hospital stay was four days. There were recurrences requiring surgery in 20 patients and recurrences not requiring surgery in three patients.

I think you must agree that from our experience pleural abrasion is not a new method. We agree, however, with the authors that it is a highly suitable technique with good results. If combined with a transaxillary approach — often an incision no more than 2 inches (5 cm) wide — it is a cosmetically acceptable form of treatment for spontaneous pneumothorax, and we will continue to use this procedure.

authors’ reply We are grateful to Drs Cole and Matar for sharing their extensive experience of surgery for pneumothorax with us. It was with some misgivings that we accepted the editorial decision to change the original title of our paper from “A safe and effective method of pleurodesis” to “New method —”. The one aspect of the technique which, as far as we are aware, has not been previously described is the use of a domestic pan scourer to achieve pleural abrasion and even this is not our invention, as it was being used by Drs Cole and MacArthur at King’s College Hospital 20 years ago. Despite the fact, however, that pleural abrasion has been in widespread use in North America and, as we now know, in Australia for many years not many surgeons using the technique routinely have published their results, and in the United Kingdom there remains the belief outside a small circle of thoracic surgeons and enlightened chest physicians that surgery for pneumothorax calls for palliative pleurectomy through a large and painful incision. Indeed, it was the inaccurate and sometimes alarming perception that many of our patients had appeared to receive that prompted us to put our experience together, and in that the subject seems now to have received a wider medical airing than before our principal objective has, in part, been fulfilled.

Shutting through a patent foramen ovale

The phenomenon of shutting through a patent foramen ovale, as recently reported by Dr I Berry and others (January 1992;47:60-1), has interested me for some time. 1

Those authors emphasised the important point that this flow was detected by transoesophageal echocardiography but not by transthoracic echocardiography — this is not recognised by all echocardiologists. A characteristic feature of this syndrome is platypnoea and orthodeoxia — that is, more pronounced breathlessness and hypoxaemia in the upright than in the supine position. Thus the shunt measurements should probably be made with the patient in the upright position if possible.

The incidence of probe patient foramen ovale is about 22%, 2 but so long as left atrial pressure exceeds right atrial pressure the valve leaflet acts as a closing flap. In the fetus the inferior vena cava empties anatomically and functionally through the foramen ovale into the left heart. In the adult a probe patent foramen ovale is most easily penetrated with a cardiac catheter passed from a femoral vein, not from the brachial vein. Unfortunately Dr Berry and her colleagues did not state which approach they used in their catheterisation.

For two reasons I doubt their explanation that the mechanism for the shunt is caused by mediastinal distortion caused by right pneumonectomy. First, above the normal anatomy favours blood flow from the inferior vena cava to the left heart when the flap is pressed open. Secondly, this flap mechanism occurs after pneumonectomy 3 and after severe respiratory failure in chronic obstructive lung disease. 4 A more likely mechanism of the different shuttling in different positions is the changing relation between the right and left pressures. This, in turn, depends on the function curves of the right and left ventricles: apparently they cross, so that at low "venous return" right atrial pressure exceeds left atrial pressure, and at a higher "venous return" left atrial pressure exceeds, or approaches, right atrial pressure.

Persistent alveolar increased permeability to 99m Tc DTPA in patients with advanced HIV infection

In their paper regarding the diagnostic value of lung clearance of 99m Tc Pneumocystis carinii pneumonia Dr D S Robinson and his colleagues (October 1991;46:722-6) emphasised the specificity of the shape of the clearance curve by noting that none of their patients who did not have pneumocystis pneumonia had a biphasic curve in both the upper and the lower zones of the lung.

We have observed three HIV infected homosexual men who died of Pneumocystis carinii pneumonia in whom 99m Tc DTPA transfer time (mean) T57p ranged from 3:1 to 4:6 (mean 4:3 minutes) and was biphasic in the upper, mid and lower zones over a follow up period of four, 18, and 31 weeks. This compares with a mean 99m Tc DTPA transfer time in five HIV patients with pneumocystis pneumonia of 3:1 (1:4) (range 1:8-9:6) minutes and a significantly lower than transfer times in HIV positive patients with various non-pneumocystis pneumonia chest condi-
