Effect of exposure to silica on human alveolar macrophages in supporting growth activity in type II epithelial cells

B Melloni, O Lesur, T Bouhadiba, A Cantin, M Martel, R Bégin

Abstract

Background – The proliferative response of type II cells is an important event following silica-induced lung injury. Alveolar macrophages, when activated by fibrogenic agents, secrete various biological mediators which affect cell growth.

Methods – Human alveolar macrophages from normal volunteers were incubated in serum-free medium or in the presence of increasing concentrations of silica. Alveolar macrophage conditioned media were diluted and added to type II cell cultures for proliferation studies. Purified type II pneumocytes were isolated from fetal rat lungs for bioassays. Growth factor activities were partially characterised by size exclusion chromatography. Each fractionated mitogenic peak was preincubated with monoclonal antibody against platelet derived growth factor (PDGF) or antisera against insulin-like growth factor 1 (IGF-1) or fibroblast derived growth factor (FGF) in order to study the nature of each activity.

Results – Conditioned media from alveolar macrophages exposed to silica induced an increase in type II cell DNA synthesis and cell number over that seen when type II cells were incubated with unstimulated alveolar macrophage supernatants. Size exclusion of alveolar macrophage supernatants exposed to silica showed four peaks of type II cell stimulating activity with apparent molecular weights of 38, 22, 16, and 8 kDa. Anti-PDGF antibody significantly reduced the activity of the first and second peaks, antiserum against IGF-1 partially reduced the activity of the first and fourth peaks, and antiserum against FGF reduced only the third peak of activity.

Conclusions – Human alveolar macrophages exposed to silica in vitro release mitogens for type II pneumocytes including PDGF-like, IGF-1-like, and FGF-like molecules. These agents are likely to be involved in the epithelial repair and type II cell hyperplasia observed in silicosis.

(Torax 1996;51:781–786)

Keywords: alveolar macrophages, silicosis, type II cells.

Proliferation of type II pneumocytes is an early event following silica-induced lung injury in animal models.1 1 Type II cell hyperplasia has been reported after exposure to high levels of silica in humans and type II cells have been found in the bronchoalveolar lavage (BAL) fluid of acutely exposed workers.2 It is established that alveolar macrophages are important cells in the pathogenesis of silicosis by releasing mediators and messengers for other cell types and for the extracellular matrix.3 4 Alveolar macrophages are the main cell found in BAL fluid from patients with subclinical or simple silicosis.5 7

We have studied the direct effect of low doses of silica on fetal type II cells in vitro,8 and have identified growth factor activity in BAL fluid from normal human lung that stimulates fetal rat type II cell growth in vitro.4 This mitogenic activity was clearly enhanced in BAL fluid from patients with early stages of silicosis. In addition, similar results were documented with BAL fluid from our experimental model of sheep silicosis. We have also found that conditioned media from alveolar macrophages of control sheep induced type II cell growth.9 Supernatants from in vitro or in vivo sheep alveolar macrophages exposed to silica significantly increased type II pneumocyte growth compared with those from non-exposed sheep alveolar macrophages. Partial characterisation of these mitogenic activities have recently been performed.2 10

It was hypothesised that human macrophages exposed in vitro to low doses of silica can be stimulated to release an increased mitogenic activity for type II cells. Factors involved in this macrophage-derived mitogenic activity are characterised in this study.

Methods

ALVEOLAR MACROPHAGE PREPARATIONS

Alveolar macrophages were obtained by bronchoalveolar lavage from 10 normal volunteers as described previously.11 The mean (SD) age of the subjects was 28 (3) years and all were non-
smokers and had not been exposed to mineral dusts. The lavage fluid was filtered through surgical gauze and centrifuged at 400g for 10 minutes. The cell pellet was suspended in Eagle's minimal essential medium (MEM; Gibco, Grand Island, New York, USA) supplemented with 10% fetal bovine serum (FBS) and antibiotics at a concentration of 2 × 10^5 cells. After one hour of adherence the cells were washed to remove non-adherent cells such as lymphocytes. Adherent cells were cultured in 24-well tissue culture plates (Falcon Inc, Lincoln Park, New Jersey, USA) in serum-free medium supplemented with 2 mM glutamine, with or without mineral dusts (see below) and incubated for 24 hours at 37°C in 5% CO₂/air. At the end of the culture period supernatants were removed, centrifuged (500g for 10 minutes), filtered through a 0.22 μm filter (Millex-GS; Millipore Corp, Bedford, Massachusetts, USA) and stored at −70°C until further use. The nature of the adherent cells was evaluated on a cytocentrifuge preparation stained with Wright-Giemsa. In all cases the resulting adherent cells were > 92% alveolar macrophages with cell viability of > 95% as assessed by exclusion of trypan blue dye.

EXPOSURE OF ALVEOLAR MACROPHAGES TO MINERAL DUSTS
Different concentrations of mineral dust particles were suspended in serum-free medium and added to macrophage cultures for 24 hours as reported previously. Silica (Minusil-5; Pennsylvania Glass Co, Pittsburgh, Pennsylvania, USA), titanium dioxide (Kronos Inc, Paris, France), or aluminum-treated quartz were heated for two hours at 200°C for sterilisation prior to use. All particles had a diameter of < 5 μm. Alveolar macrophage conditioned media were routinely checked for endotoxin contamination by the limulus amebocyte assay (Sigma, St Louis, Missouri, USA). The alveolar macrophage supernatants were filtered through a 0.45 μm filter and stored at −20°C until required for cell proliferation assays.

EVALUATION OF SILICA DUST PARTICLES IN ALVEOLAR MACROPHAGES
The number of particles in alveolar macrophages was evaluated by polarised light microscopy. Quantification of the particles in the former evaluation was carried out by counting 500 cells for each sample with three independent determinations.

DUST CYTOTOXICITY ON ALVEOLAR MACROPHAGES
Lactate dehydrogenase (LDH) release in culture medium was quantified to determine dust cytotoxicity on macrophages after incubation for 24 hours. These cells exhibited an immuno-cytochemical staining for cytokeratin 19, an intermediate filament specific to epithelial cells. Type II cells were used at passage 2 and were rendered quiescent by a 48 hour incubation in “breaking medium” (MEM) containing 2% serum (heat inactivated FBS). Conditioned media from alveolar macrophages exposed or not exposed to mineral dusts were added to the pneumocyte cultures. Given the log phase between DNA synthesis and cell division, cell growth was evaluated by the incorporation of tritiated thymidine at 24 hours and by counting the monolayers at 48 hours.

PARTIAL CHARACTERISATION OF THE MACROPHAGE-DERIVED MITOGENIC ACTIVITIES
To produce sufficient amounts of growth promoting activity for partial purification, adherent cells from six normal individuals were incubated in serum-free medium supplemented with 50 μg/ml silica particles. This latter concentration induced the higher mitogenic activity on type II cells.

Gel filtration
Pooled alveolar macrophage supernatants from six healthy volunteers were lyophilised, concentrated 50-fold, and reconstituted in 1 ml sterile phosphate buffered saline (PBS) as previously reported. Gel filtration was performed on a G-75 SF column (Pharmacia Inc, Baie d’urfe, Quebec, Canada) at a flow rate of 0.75 ml/min and 2.5 ml fractions were collected. The eluate was monitored by absorbance reading at 280 nm. Fifty four fractions were diluted 1:2 in MEM supplemented by 2% serum and tested in type II cell DNA synthesis assays.

Biophysical properties of macrophage-derived mitogenic peaks
To study the properties of the alveolar macrophage derived growth activity, adjacent fractions with maximum activity for type II cells were pooled, lyophilised, and resuspended in medium as described above.

Acid treatment: Aliquots of mitogenic peak were dialysed against 1 M acetic acid (pH 2.5, three changes, 24 hours), followed by dialysis against MEM.

Heat treatment: Aliquots of mitogenic peak were incubated at 100°C or 56°C for 30 minutes and then cooled at room temperature.

Role of reducing agent: Aliquots of mitogenic peak were incubated with 2 mM dithiothreitol for 30 minutes at 37°C and dialysed against 1000 volumes of MEM (three changes, 24 hours).

Sensitivity to protease reduction: Aliquots of mitogenic peak were incubated with 1700 BAE units of trypsin (type IX, 30 minutes, 37°C) followed by incubation with twice the concentration of soybean trypsin inhibitor.

All treated aliquots were tested on type II cell [³H]-thymidine incorporation and compared with an untreated aliquot prepared by the same process. All treated aliquots and controls were filtered prior to assay on type II cell cultures.

Blocking antibodies
Preincubation of 50 ng/ml human recombinant platelet-derived growth factor antibody (PDGF) with 50 μg/ml anti-PDGF IgG (Anti-
PDGF, Collaborative Research Inc, Bedford, Massachusetts, USA) completely blocked the ability of this cytokine to stimulate [3H]-thymidine incorporation by type II cells.11 G-75 mitogenic peaks were preincubated with monoclonal anti-PDGF IgG prior to the determination of mitogenic activity. Rabbit polyclonal antiserum to human recombinant insulin-like growth factor I and to fibroblast growth factor from bovine pituitary extracts (IGF-I and FGF, Collaborative Research Inc) were produced by immunisation of New Zealand white rabbits with IGF-I emulsified in Freund's adjuvant. Rabbit antiserum to IGF-I completely blocked the activity of 1 μg/ml IGF-I on type II cell DNA synthesis at a dilution of 1:500, and rabbit antiserum to FGF at a dilution of 1:2000 completely blocked the effect of 500 ng/ml FGF on type II cell DNA synthesis. We have previously shown11 that each blocking antibody or antiserum is specific for the corresponding cytokine.

**Statistical Analysis**

Data are expressed as mean (SE). Statistical significance (p < 0.05) was determined by analysis of variance (ANOVA) and a Student's t test for comparison with control data.

**Results**

**Effect of In Vitro Silica Dust Exposure on Alveolar Macrophages**

Increasing concentrations of silica induced a higher release of LDH than under control conditions (fig 1); low doses of silica did not provoke a significant release of LDH. Treatment with titanium dioxide or aluminum-treated silica did not increase LDH release.

**Evaluation of Silica Particles in Alveolar Macrophages**

Dust particles were rarely found in alveolar macrophages of control patients (2 (1%) of total cells). A linear relationship between dust concentration and the percentage of adherent macrophages containing silica particles was found when silica was incubated with alveolar macrophages for 24 hours (8 (2%) at 25 μg/ml, 14 (4%) at 50 μg/ml, 22 (5%) at 100 μg/ml).

**Effect of Macrophage Supernatants on Type II Cell Growth**

The effects of macrophage conditioned media were tested for their ability to induce the growth of fetal rat type II cells in vitro. Conditioned media were prepared from macrophages exposed to various concentrations of silica (fig 2). Macrophages were incubated with conditioned media for 24 hours, and the number of viable cells was determined by tritiated thymidine incorporation and cellular proliferation assessed by cell counting. The results showed that silica exposure significantly increased thymidine incorporation in macrophages, with the highest effect at 50 μg/ml. This effect was dose-dependent, with a significant increase observed at 10 to 50 μg/ml (10 μg/ml: r² = 0.14, 25 μg/ml: r² = 0.54, 50 μg/ml: r² = 0.28, p < 0.05).

**Figure 1** Release of lactate dehydrogenase by human alveolar macrophages exposed in vitro for 24 hours to silica, aluminum-treated silica, and titanium dioxide. *p < 0.05 compared with control value.

**Figure 2** Comparison of the effect of supernatants from unstimulated macrophages (C) and macrophages exposed to silica in vitro ( ●) on incorporation of [3H]-thymidine into type II cells. *p < 0.05 versus unstimulated macrophage supernatants. Correlations between thymidine incorporation and cellular proliferation assessed by cell counting were significant as silica concentrations from 10 to 50 μg/ml (10 μg/ml: r² = 0.14, 25 μg/ml: r² = 0.54, 50 μg/ml: r² = 0.28, p < 0.05).

Neutralising antibodies in mitogenic peaks

Antibody against PDGF and antisera against IGF-1 and FGF were used to block the mitogenic activity of each peak fractionated from silica-exposed macrophage supernatants (table 2). A significant part of the mitogenic activity of the first and second peaks was inhibited by anti-PDGF IgG (40% for the first peak and 27% for the second peak). Anti-IGF-1 antiserum substantially reduced the activity of the first (37%), second (26%), and fourth (35%) peaks of activity; anti-FGF antiserum affected the mitogenic activity of all peaks, but only that of the third peak (50%) to a significant extent. Several combinations of anti-PDGF IgG and antisera against IGF-1 or FGF were tested and a synergistic neutralising effect on the second peak (46%) was shown by the combination of anti-PDGF with anti-IGF-1. On the other hand, the addition of either anti-PDGF antibody or antiserum against IGF-1 or FGF alone to unfractionated conditioned media had no effect on type II cell DNA synthesis (data not shown).
Effect of exposure to silica on human alveolar macrophages

Discussion

Many recent studies have focused on the ability of inorganic particles to induce secretion of fibroblast mitogenic activities by macrophages in vitro. Macrophages isolated from patients exposed to silica dust released in vitro an alveolar macrophage-derived progression growth factor which is involved in fibroblast regulation and has been shown to be an IGF-1 molecule with a molecular weight of 18–25 kDa. Type II cell hyperplasia in animal models appears to be an early event following type I epithelial damage and this also appears to be a feature of human silicosis. In this study the nature of the mitogenic activities for type II cells released by human alveolar macrophages incubated in vitro with low doses of silica was investigated.

We have previously explained the choice of fetal rat type II cells for bioassays. Earlier studies have shown that fetal rat type II cells were differentiated at 19 days and expressed different markers of alveolar epithelial cells. Most importantly, fetal type II cells are able to divide in cultures and the cell numbers are strictly correlated with DNA synthesis in our model. Of the well known mitogenic factors, PDGF, FGF, and IGF-1 stimulate fetal type II cell growth in vitro, and these are released spontaneously by activated alveolar macrophages.

Our results indicate that supernatants from human alveolar macrophages exposed to silica in vitro induced a significantly greater increase in fetal type II cell growth than that seen with supernatants from unstimulated adherent macrophages. This effect is specific for silica particles and was not observed with inert dust/titanium dioxide or modified dust/aluminum-treated silica. Importantly, low doses of silica induced the highest growth factor activity. This observation confirms the results previously reported with macrophages exposed in vitro or in vivo to silica. Activation of macrophages by silica could stimulate their production of macrophage derived growth factor for type II cells. The percentage of macrophages in the BAL fluid that contained particles of silica dust was 52% in the subjects exposed to silica and only 6% in control subjects. A non-cytotoxic concentration of 50 μg/ml of silica was used for partial characterisation in our experiments. At this concentration, only 14% of the cells contained cytoplasmic mineral particles.

Pneumoconioses are characterised by an alveolitis rich in alveolar macrophages. The release of soluble mediators from alveolar macrophages in patients with silicosis has been involved in the pathogenesis of inflammation and fibrosis. It is well established that the interaction between macrophages and silica is an early event in the inflammatory response to mineral dust. In addition, alveolar type II cell proliferation is an important process which occurs after most types of lung injury including exposure to silica dust. The mechanisms that regulate alveolar type II cell proliferation in lung injury are poorly understood. We have documented a proliferative activity for fetal type II cells in BAL fluid from healthy volunteers in our previous studies and have shown that this activity was significantly enhanced in BAL fluid from patients exposed to silica which suggests that the mitogenic activity of epithelial cells in the BAL fluid could at least partly be released by macrophages. These findings are consistent with previous reports which have shown that conditioned media from rat or human alveolar macrophages stimulated adult rat type II cell DNA synthesis. The BAL fluid from normal rats induced DNA synthesis in adult rat type II cells. A recent study has characterised the nature of the alveolitis in the lower respiratory tract of patients with pneumoconiosis. Alveolar macrophages from subjects exposed to asbestos or silica spontaneously release mitogenic activity for lung fibroblasts and fibronectin, an important component of the extracellular matrix. In a recent study of patients with coal workers’ pneumoconiosis the production of PDGF, IGF-1, and transforming growth factor β(TGF-β) was demonstrated in alveolar macrophage supernatants and the role of PDGF and IGF-1 was associated with fibroblast growth.

Partial characterisation of these mitogenic activities for type II cells was performed and size exclusion chromatography showed four distinct peaks of growth promoting activity in alveolar macrophage supernatants exposed to silica. Most of the four distinct peaks of activity were lost with trypsin treatment, suggesting a proteinic nature. The first and second peaks of apparent molecular weights of 38 kDa and 22 kDa, respectively, were resistant to acid and heat and were also partially inhibited by the anti-PDGF IgG. These results suggest that these factors could be PDGF-like molecules or that they are closely related to IGF-1 molecules. IGF-1 is an 18 kDa mediator implicated in growth and shares similarities with PDGF or IGF-1 molecules. Antiserum against IGF-1 partially inhibited the activity of the first and second peaks, and the combination of anti-PDGF with anti-IGF-1 was synergistic in blocking the activity of the second peak. The third peak of type II cell mitogenic activity has an apparent molecular weight of 16 kDa and was sensitive to acid and heat and was considerably reduced by preincubation with antiserum against FGF. This activity could be an FGF-like molecule or a cleavage product of another peptide. The fourth activity peak has a small molecular weight of 8 kDa which was also acid-sensitive and partially reduced by preincubation with antiserum against IGF-1. In this area the 7 kDa bloodstream form of IGF-1 could be implicated, or other peptides which are known to induce fetal type II cell growth could be suspected such as EGF and TGF-α.

The nature of the mitogenic activities for epithelial cells is not completely characterised by these conventional methods because of difficulties with the induction of secretion of growth factors by alveolar macrophages in the artificial environment of cell culture and the differences between species. Furthermore, the
activities of combinations of cytokines are complex and cannot be predicted from the activity of each individual cytokine.18

PDGF has been identified as a cationic protein with an apparent molecular weight of 28–35 kDa. It is known to behave as two distinct peptide chains (chains A and B) that are synthesised in high molecular weight precursors and are processed before secretion. On the other hand, PDGF-like activities are detected in vitro in conditioned media from various cells such as macrophages. There are many differences in the molecular weights of PDGF isoforms. Monomeric forms outline the existence of a growing family of related cytokines, the so-called PDGFs. The partial purification of PDGF-like activity can be attributed to the presence of different PDGF isoforms. The characterisation may also be confused by the presence of circulating binding proteins which can modify the apparent molecular weight of these factors.23 25 Hence, purification of IGFs reveals a larger molecular weight in relation to the combination of IGFs to their binding proteins. IGF-1 is a peptide of 7.6 kDa in serum and 18 kDa in macrophage supernatants, but the highest molecular weight of 38 kDa corresponds with the IGF binding protein.25 The existence of IGF binding proteins in conditioned media could explain our results. Secretion of growth factors in vivo may be driven by mediators secreted by other cells such as lymphocytes which participate in the inflammatory response to silica,26 but these mediators may not be present in vitro experiments with macrophages in BAL fluid. Nevertheless, the results of our study are in agreement with previous data that have shown that alveolar macrophages exposed to mineral dust release cytokine-like activity.

In conclusion, this study has confirmed that mitogenic factors for type II cell growth in vitro are produced by macrophages exposed to silica. Macrophages activated by silica phagocytosis could play a key regulatory role in alveolar epithelial repair. Of the known growth factors, PDGF-like, IGF-1-like, and FGF-like molecules could be implicated in the regulation of type II cell growth after lung injury. Further investigations are required to analyse this non-specific response to silica at a molecular level.
