Introductory article

Prevention of respiratory complications after abdominal surgery: a randomised clinical trial

JC Hall, RA Tarala, J Tapper, JL Hall

Objective. To evaluate the prevention of respiratory complications after abdominal surgery by a comparison of a global policy of incentive spirometry with a regimen consisting of deep breathing exercises for low risk patients and incentive spirometry plus physiotherapy for high risk patients. Design. Stratified randomised trial. Setting. General surgical service of an urban teaching hospital. Patients. 456 patients undergoing abdominal surgery. Patients less than 60 years of age with an American Society of Anaesthesia classification of 1 were considered to be at low risk. Outcome measures. Respiratory complications were defined as clinical features consistent with collapse or consolidation, a temperature above 38°C, plus either confirmatory chest radiology or positive results on sputum microbiology. We also recorded the time that staff devoted to prophylactic respiratory therapy. Results. There was good baseline equivalence between the groups. The incidence of respiratory complications was 15% (35/231) for patients in the incentive spirometry group and 12% (28/225) for patients in the mixed therapy group (P = 0.40; confidence interval –3.6% to 9.0%). It required similar amounts of staff time to provide incentive spirometry and deep breathing exercises for low risk patients. The inclusion of physiotherapy for high risk patients, however, resulted in the utilisation of an extra 30 minutes of staff time per patient. Conclusions. When the use of resources is taken into account, the most efficient regimen of prophylaxis against respiratory complications after abdominal surgery is deep breathing exercises for low risk patients and incentive spirometry for high risk patients. (BMJ 1996;312:148-53)

Postoperative respiratory morbidity continues to be a major factor in the utilisation of resources and maintenance of hospitalisation after major surgery. The introductory article draws attention to this but, as the aetiology, prevention and management are multifactorial, the approach of this review to this subject has been broadened.

The incidence of pulmonary complications is higher after upper abdominal or chest surgery than operations on other parts of the body. These wounds produce a severe and prolonged alteration in pulmonary mechanics. Impaired ventilation and ineffective expectoration result in a postoperative failure of expansion or progression of collapse of lung segments, thereby encouraging infection. The ensuing shunt with venous admixture results in hypoxaemia. Postoperative oxygen supply may therefore falter while oxygen demands are increased due to metabolic hypermetabolism and hypercatabolism of the neuroendocrine stress response to trauma. At the same time the work of breathing is increased due to the need for increased alveolar ventilation (because of shunt induced carbon dioxide retention), a stifferened abdominal wall and, possibly, diaphragmatic dysfunction. These pathophysiological changes underpin the events in the immediate postoperative period and morbidity and mortality depend upon their severity. The main factor behind all these events, and the one which is most amenable to modification, is severe postoperative pain.

This discussion paper will review the effects of anaesthesia and an abdominal incision on pulmonary physiology. Some great minds have pondered the problem of postoperative complications. Pasteur, Haldane and Beecher were all convinced of the importance of active collapse of the lung after abdominal operations with shallow breathing as the major cause of postoperative hypoxia and pulmonary complications.
INTRAOPERATIVE AND POSTOPERATIVE CHANGES IN LUNG VOLUMES

Major alterations occur in respiratory volumes in all patients following abdominal surgery, involving a decrease in functional residual capacity (FRC) but with minimal change in the closing volume (CV). When CV exceeds FRC, atelectasis in the dependent lung regions becomes inevitable. This change is most exaggerated in the elderly, the obese, in smokers, and in those with pre-existing cardiopulmonary disease. General anaesthesia, irrespective of the anaesthetic agents used, causes a reduction in FRC of approximately 18% (the only possible exception being ketamine). Body posture affects lung volumes, with a change from supine to sitting increasing CV only slightly but increasing FRC significantly. Thus, in the immediate postoperative period the sitting position is preferred and early mobilisation is to be actively encouraged. Sufficiently effective analgesia must be established and maintained so that these activities are not impeded by pain.

ALTEDERED VENTILATORY PATTERN

Alterations in ventilatory mechanics occur both during surgery and for a long period of time afterwards. The characteristic postoperative mechanical abnormality in respiration is a restrictive pattern of ventilation with a significant reduction in vital capacity (VC), tidal volume (VT), forced expiratory volume in one second (FEV1), and FRC, and the principal cause of these abnormalities is pain. No other factor has greater importance. To compensate for the reduced efficiency of breathing, carbon dioxide retention, and reduced VT there is an increase in respiratory rate. Minute ventilation is maintained or increased at the expense of an increase in the work of breathing and therefore oxygen demand. The postoperative use of sedatives and opiates impairs the natural sigh mechanism which is responsible for maintaining small airways patency and FRC. Spontaneous deep breaths which help to restore FRC are abolished by a combination of pain and narcotic analgesics.

ALTERATIONS IN GAS EXCHANGE

Gas exchange is impaired intraoperatively due to a ventilation/perfusion mismatch which persists long into the postoperative period. It is the accepted view in the literature that this phenomenon of postoperative hypoaxemia in the absence of hypoventilation is inevitable. Physical therapy is of importance in that removal of secretions and re-expansion of collapsed basal lung segments will restore gas exchange.

Postoperative hypoaxemia resulting from the respiratory abnormalities discussed above is often compounded by systemic opiates. Complications such as myocardial infarction and insufficiency, pulmonary complications, cerebrovascular accidents, thrombembolic phenomena, and thermal damage (by the cutting diathermy) to some internal organs (visceral pain). This nociceptive pathway, even when a different nociceptors and by their sensitisation normalities is pain. No other factor has greater importance. The latter two structures are thought to have little importance but the sympathetic chain may have a major role. Activation of peripheral nociceptors leads to hyperexcitability of neurones in spinal cord dorsal horns. Sensitisation of the dorsal horn cells links with sensitisation in injured tissues to form a self-sustaining nociceptive pathway, even when afferent stimuli from injured tissues begin to subside. The overall consequences of these central changes are a reduction in pain thresholds to the extent that non-painful stimuli are interpreted as pain, an expansion of cutaneous receptor fields so that the extent of the painful area is increased, and spontaneous and ongoing activity within the dorsal horn and the CNS so that chronic pain can ensue.

CO = cardiac output; VR = systemic vascular resistance.
Pain management

As the respiratory abnormalities discussed above set the stage for postoperative respiratory complications, it is vitally important to attempt their amelioration, as it is the pulmonary function that is invariably the main factor responsible for these changes. Inadequate analgesia prevents early ambulation and deep breathing and prolongs hospital stays. As pain is not only the main factor responsible for these changes, but is the main causative factor open to modulation, it is critically important that the analgesic method chosen which can best improve pain and pulmonary function. Effective analgesia will improve and even reverse the effects of surgery on the pulmonary mechanics and prevent pulmonary complications.\[^{13-16}\]

Reliance upon systemic opiates as the mainstay of an analgesic regime for the control of pain following major abdominal surgery is misguided. Opiates are at best protective analgesia will improve and even reverse the effects of surgery on the pulmonary mechanics and prevent pulmonary complications.\[^{13-16}\]

The surgeons’ response to all these sequelae is to minimise the attering input to the CNS through the use of laparoscopic surgery in preference to laparotomy. This has led to a revolution in surgical practice. However, clinical outcome data supporting this approach are poor. Most prospective studies have not been randomised and reality are small audits of results.

Minimally invasive surgery

NSAID = non-steroidal anti-inflammatory drug.
formed in patients undergoing appendectomy which showed no difference. A further study has shown a reduction in the length of hospital stay, but with no difference in complications. Physician controlled discharge times are a poor indicator of superiority of one treatment over another.

There are insufficient data to assess open versus laparoscopic pyloromyotomy as only one study has been performed of which the results were almost equivocal. Four prospective randomised studies of inguinal hernia repair have been undertaken. One showed less pain and reduced postoperative complications in the laparoscopic group, but the recurrence rate will not be known for a number of years. Two others concluded that a laparoscopic approach was as good as an open approach, although the operative costs were higher. The third was difficult to interpret as the open group had local anaesthesia compared with general anaesthesia for the laparoscopic group, although the results were strongly and significantly in favour of the open approach. Laparoscopic cholecystectomy seems to be the indication for this approach which has been most studied. In one randomised study of open cholecystectomy versus endoscopic splincterotomy no differences were found in mortality and morbidity, but there was a higher recurrence of symptoms with the endoscopic approach, leading to the conclusion that open surgery was preferable.

In a prospective randomised comparison of laparoscopic versus small incision cholecystectomy involving 200 patients Majeed et al found that the laparoscopic approach took longer to do and had no significant advantages in terms of hospital stay or postoperative recovery. MCM ahon found that laparoscopic cholecystectomy led to shorter hospital stays and a quicker return to normal activities than an open approach, but there was no difference in the incidence of complications and operative costs were higher. Pulmonary function in terms of spirometric values and oxygenation has been shown to be better in laparoscopic than in laparotomy cholecystectomy in a number of studies.

Very little attempt was made in these studies to utilise regional analgesia which, in our view, is difficult to justify when all the inadequacies of systemic opiates are taken into account. Rademaker et al did use epidural analgesia in a comparison of pulmonary function and stress responses in laparoscopic versus substernal incision cholecystectomy. Oddly perhaps, epidural analgesia was used in one of the laparoscopic groups rather than the substernal incision group. The laparoscopic groups did better in terms of pulmonary function even though the endocrine stress response was similar. Local anaesthetics with laparoscopic cholecystectomy have been used intraperitoneally with two opposing views of their efficacy. It seems that, with fairly substantial doses given immediately after induction of the pneumoperitoneum and repeated at the end of surgery, pain can be reduced. A fully comprehensive review of studies undertaken with laparoscopic cholecystectomies has been made by Downs et al. Laparoscopic-assisted ileal pouch anal anastomosis compared with standard laparotomy failed to reduce the duration of postoperative ileus or length of hospital stay.

We are forced by these data to question the philosophy of the seemingly headlong rush into minimally invasive surgery.

**MODIFICATION OF PREDICTIVE RISK FACTORS**

Studies on the effectiveness of modification of risk factors on outcomes are difficult to interpret due to the defining criteria used. The incidence of pulmonary complications varies enormously after abdominal and chest surgery. Important diagnostic criteria should include sputum changes, abnormalities in auscultation, radiological changes, fever, leucocytosis, and hypoxemia.

Smoking has the effect of reducing fed 10 years to one's age so that the functional consequences of airways closure during tidal breathing will occur earlier and to a greater extent in smokers than in non-smokers. Chronic obstructive pulmonary disease is associated with copious production of viscid sputum which leads to obstruction of airways with distal collapse and exacerbated shunting. Cessation of smoking improves lung function by approximately one month and improvement continues for up to 18 months. Even a few days abstinence will improve mucociliary transport. Obesity causes a restrictive defect in pulmonary function because of a reduction in chest wall compliance, all lung volumes, including FRC, being affected. If surgery is elective then obese patients should be encouraged to lose weight.

Muscular strength should be maintained as far as possible in the malnourished or hypercatabolic patient through adequate nutrition.

**PREDICTORS OF PULMONARY COMPLICATIONS**

A number of studies have tried to identify predictors of pulmonary complications. In a study of 278 patients pre-existing respiratory morbidity and poor exercise tolerance were found to be predictors of morbidity whereas pulmonary function test results in this respect were unhelpful. However, in a study of patients undergoing thoracotomy for oesophagectomy VC was found to correlate positively with the risk of complications.

**Physical therapy**

Physical therapy has a valuable role to play in the prevention of complications as well as their treatment, although the type of therapy which should be used is not entirely clear. Various methods of physical therapy have been shown to improve measured pulmonary function – for example, VC and FRC and a meta-analysis showed a significantly beneficial effect on the prevention of complications. However, single treatment modalities – for example, incentive spirometry, coughing and breathing exercises and intermittent positive pressure breathing – have yet to have their individual roles defined.

In their study of 456 patients undergoing abdominal surgery Hall et al found a small and non-significant reduction in complications from 15% for high and low risk patients given incentive spirometry versus 12% in low risk patients given breathing exercises and incentive spirometry along with conventional physiotherapy in high risk patients. This small improvement was thought to be worth the investment in terms of utilisation of manpower resources, although the addition of conventional physiotherapy added significantly to staff time.

In conclusion, major alterations in pulmonary mechanics and ventilation/perfusion relationships result from anaesthesia and abdominal surgery and the principal inhibitor of chest cage motion is severe postoperative pain. Atelectasis, hypoxaemia, infection, and respiratory...
Prevention of respiratory complications after abdominal surgery

LEARNING POINTS

- The incidence of pulmonary complications is higher after upper abdominal or chest surgery than operations on other parts of the body due to a severe and prolonged alteration in pulmonary mechanics.

- The sitting position increases FRC significantly and early mobilisation is to be actively encouraged. Sufficiency effective analgesia must be maintained so that these activities are not impeded by pain.

- It is critically important that the analgesic method chosen is one that can best improve pain control and lung function. Effective analgesia will improve the detrimental effects of surgery on pulmonary mechanics and prevent pulmonary complications.

- Physical therapy has a valuable role to play in the prevention of respiratory complications as well as their treatment, although the relative values and indications for different therapies have still to be conclusively determined.
