Introductory article

The health care costs of smoking

JJ Barendregt, L Bonneux, and PJ van der Maas

Background. Although smoking cessation is desirable from a public health perspective, its consequences with respect to health care costs are still debated. Smokers have more disease than nonsmokers, but nonsmokers live longer and can incur more health costs at advanced ages. We analyzed health care costs for smokers and nonsmokers and estimated the economic consequences of smoking cessation.

Methods. We used three life tables to examine the effect of smoking on health care costs—one for a mixed population of smokers and nonsmokers, one for a population of smokers, and one for a population of nonsmokers. We also used a dynamic method to estimate the effects of smoking cessation on health care costs over time. Results. Health care costs for smokers at a given age are as much as 40 percent higher than those for nonsmokers, but in a population in which no one smoked the costs would be 7 percent higher among men and 4 percent higher among women than the costs in the current mixed population of smokers and nonsmokers. If all smokers quit, health care costs would be lower at first, but after 15 years they would become higher than at present. In the long term, complete smoking cessation would produce a net increase in health care costs, but it could still be seen as economically favorable under reasonable assumptions of discount rate and evaluation period. Conclusions. If people stopped smoking, there would be a savings in health care costs, but only in the short term. Eventually, smoking cessation would lead to increased health care costs. (N Engl J Med 1997;337:1052–7)

Smoking related diseases cost the British National Health Service (NHS) somewhere between £1.4 billion and £1.7 billion every year. It is hardly surprising, therefore, that reductions in these health care costs should be highlighted as a major benefit of smoking cessation. However, non-smokers live longer than smokers. In the USA 78% of male non-smokers are still alive at the age of 70 compared with 57% of smokers. At the age of 80 the figures are 50% and 21%, respectively. Non-smokers thus impose a greater burden on health care resources in old age than their shorter lived fellow citizens who smoke. This has led to much recent research into who has the greater lifetime health care costs, the smoker or the non-smoker? In the introductory article Barendregt and colleagues conclude that, despite the short term savings to society from smokers quitting, the long term effect will be a net increase in health care costs.

The public health policy implications of this conclusion require several additional issues to be addressed, including the key question—so what? Barendregt and colleagues quite rightly point out that the primary objective of health policy is not to save money, and therefore evaluation of policy measures cannot be on the basis of whether or not they produce net resource savings: “... in formulating public health policy, whether or not smokers impose a net financial burden ought to be of very limited importance” (page 1057). A more appropriate health policy objective is to increase life years and improve health related quality of life. What matters, therefore, is how the cost of achieving these health gains through smoking cessation interventions compares with the cost of achieving them by other means.

It was not the intention of the Barendregt study, nor is it the intention of the present review, to address that question. Reviews of the cost effectiveness of smoking cessation are available elsewhere. Here, the focus is on the cost to society of smoking cessation. We shall address this by critically examining the approach and assumptions of the Barendregt study with respect to health care costs of smoking, and by considering the wider economic implications of changing smoking habits, since the financial costs of smoking are not confined to health service resource use.

Does the introductory article underestimate the health care costs of smoking? The estimate which Barendregt and colleagues provide for the lifetime health care costs of smokers and non-smokers is based on the incidence, prevalence, and
mortality associated with five major categories of smoking related diseases, and the relevant “rate ratios” (differences in frequency of disease between smokers and non-smokers) derived from the literature. These five major categories comprised: heart disease, stroke, lung cancer, a heterogeneous group of other cancers, and chronic obstructive pulmonary disease.

This approach is a wholly appropriate one which will capture the bulk of the extra health care costs of smoking. There are, however, several reasons why such an approach will understate the true extra costs of smoking. These we shall discuss further.

**Health care costs of other smoking related diseases**

While accepting that the five categories of disease used in the Barendregt study represent the bulk of smoking related morbidity and mortality, and hence the majority of health care costs, the list of other diseases in which smoking has been implicated is long and growing. Omission of these other smoking induced diseases thus underestimates the true health care costs of smoking. For example, there is mounting evidence of a relationship between smoking and the incidence of cataract, with a relative risk for smokers of more than 20 cigarettes per day as high as 2.16. Given that over 1.1 million cataract operations were performed in the USA in 1989 and that reimbursement for these procedures accounts for approximately 12% of the Medicare budget, the extent of the extra health care costs in this area is clearly considerable.

Evidence of an increased risk of hip fractures in smokers has also been reported. A recent meta-analysis suggests that bone density diminishes after the age of 50 leading to an increased risk of hip fracture for current smokers of 17% at age 60, 41% at age 70, and 108% at age 90. Again, given the high volume of hip fracture operations this translates into considerably increased health care costs.

**Health care costs of delayed recovery from non-smoking related conditions**

There is evidence that smoking inhibits recovery from a number of non-smoking related conditions. It has been shown to be a risk factor for increasing the time patients spend in a post-anaesthesia care unit (PACU) following a wide range of surgical procedures. Thirty-eight percent of non-smokers were discharged from the PACU less than one hour after admission compared with only 23% of smokers. Similar problems have been reported for delayed wound healing. They have been explained by nicotine, carbon monoxide, and hydrogen cyanide undermining expeditious wound repair.

**Health care costs of passive smoking**

The Barendregt study assumed that smoking induced disease is confined to smokers. This ignores mounting evidence of the health effects of passive smoking on non-smokers. In the USA the Environmental Protection Agency (EPA) attributed 53,000 deaths of non-smokers each year to passive smoking. A subsequent report estimated this risk enhancement to be even higher at 53% for Russian women whose husbands smoke. Similarly, a 23% increased risk of ischemic heart disease has been shown for lifelong non-smokers who live with smokers rather than non-smokers. Passive smoking is also associated with a 25% increase in the risk of acute respiratory illness.

Children whose parents smoke have an increased risk of a wide range of respiratory illnesses. In the USA an EPA report estimated that the respiratory health of between 200,000 and one million asthmatic children is worsened by exposure to environmental tobacco smoke. An excess of hospital attendances (which were attributed to environmental tobacco smoke) suggested that children of smoking mothers had incurred health expenditures for respiratory illness at a rate more than two and a half times that of children of non-smoking mothers.

The direct annual medical expenditure for early childhood respiratory illness attributable to smoking is estimated to be over $100 million. However, the indirect health care costs due to other health related factors associated with smoking had also played a role. The direct annual medical expenditure for early childhood respiratory illness attributable to smoking is estimated to be over $100 million. However, the indirect health care costs due to other health related factors associated with smoking had also played a role.

**Health care costs of birth outcomes due to smoking whilst pregnant**

In a series of meta-analyses DiFranza and Lew estimated that each year in the USA smoking during pregnancy is responsible for 19,000-141,000 abortions, and that reimbursement for these procedures accounts for approximately 12% of the Medicare budget, the extent of the extra health care costs in this area is clearly considerable.

Evidence of an increased risk of hip fractures in smokers has also been reported. A recent meta-analysis suggests that bone density diminishes after the age of 50 leading to an increased risk of hip fracture for current smokers of 17% at age 60, 41% at age 70, and 108% at age 90. Again, given the high volume of hip fracture operations this translates into considerably increased health care costs.

**Health care costs of delayed recovery from non-smoking related conditions**

There is evidence that smoking inhibits recovery from a number of non-smoking related conditions. It has been shown to be a risk factor for increasing the time patients spend in a post-anaesthesia care unit (PACU) following a wide range of surgical procedures. Thirty-eight percent of non-smokers were discharged from the PACU less than one hour after admission compared with only 23% of smokers. Similar problems have been reported for delayed wound healing. They have been explained by nicotine, carbon monoxide, and hydrogen cyanide undermining expeditious wound repair.

**Health care costs of passive smoking**

The Barendregt study assumed that smoking induced disease is confined to smokers. This ignores mounting evidence of the health effects of passive smoking on non-smokers. In the USA the Environmental Protection Agency (EPA) attributed 53,000 deaths of non-smokers each year to passive smoking. A subsequent report estimated this risk enhancement to be even higher at 53% for Russian women whose husbands smoke. Similarly, a 23% increased risk of ischemic heart disease has been shown for lifelong non-smokers who live with smokers rather than non-smokers. Passive smoking is also associated with a 25% increase in the risk of acute respiratory illness.

Children whose parents smoke have an increased risk of a wide range of respiratory illnesses. In the USA an EPA report estimated that the respiratory health of between 200,000 and one million asthmatic children is worsened by exposure to environmental tobacco smoke. An excess of hospital attendances (which were attributed to environmental tobacco smoke) suggested that children of smoking mothers had incurred health expenditures for respiratory illness at a rate more than two and a half times that of children of non-smoking mothers. It could be, however, that socioeconomic factors associated with smoking had also played a role. The direct annual medical expenditure for early childhood respiratory illness attributable to smoking is estimated to be over $100 million. However, the indirect health care costs due to other health related factors associated with smoking had also played a role.
lower socioeconomic status, have a lower level of education, take less exercise, eat a less healthy diet, and consume more alcohol than non-smokers. All of these are associated with higher morbidity and mortality and, taken together, suggest that a population of smokers who quit would continue to have higher health care costs than a population of non-smokers, even in the long term. In this respect, then, the introductory article may have overestimated the true health care cost of smoking.

Other (non-health care) costs of smoking
While the question addressed in the Barendregt study was limited to differences in lifetime health care costs between smokers and non-smokers, there are other costs (and benefits) which smoking imposes on the economy. There is no reason in principle why these costs should be regarded as any less relevant to society than health care costs.

Costs to industry from smoking related absences
Smoking is a major cause of sickness absence which imposes major costs on industry from lost productivity. In the UK approximately 50 million working days are lost each year due to smoking, valued at £7170 million. This is more than the estimated cost of smoking to the NHS.

US smokers are absent from work approximately 6.5 days more per year than non-smokers. Costs of lost productivity of persons disabled by smoking related diseases and forfeited earnings of those dying prematurely of such diseases have been put at $47 billion per year. To this should be added another $8.6 billion of lost productivity due to passive smoking.

The processes which give rise to absence from the workplace, however, are complex. The simple observation of higher rates of absence among smokers may therefore be insufficient to establish a causal connection between smoking and absence from work. In a recent study Bush and Wooden showed that morbidity alone cannot fully explain the higher sickness absence of smokers, and speculated that some behavioural characteristics associated with smokers may be partly responsible. Nevertheless, even after controlling for numerous health indicators (alcohol, exercise, weight), job characteristics (employment status, hours worked, income, occupation), and demographic characteristics (age, sex, ethnicity, marital status, education, place of residence), the study still showed smoking status to be highly correlated with absence from work.

Although it would be wrong to suggest that the whole cost of the higher absenteeism of smokers is due to their smoking induced morbidity, the further cost to society from smoking is both real and important. Even if lifetime health care costs are greater for non-smokers than smokers (as Barendregt and colleagues suggest), the difference is more than offset by the gain in lifetime work productivity. This suggests that the economic benefit of smoking cessation will be positive (and large) regardless of the net effect on health care costs.

Other costs of smoking
In the UK fires caused by cigarette smoking have been estimated to cost £20 million per annum. In the USA such fires are the leading cause of civilian fire deaths (2300 deaths per year) with an additional 8000 injuries per year. In addition to the health care costs of treating burn victims, property damage from fires caused by cigarettes has been valued at $532 million per year.

Beneficial economic effects of smoking
Any assessment of the economic costs of smoking, and the potential economic benefits of cessation, would be incomplete unless it also took account of the positive economic effects of smoking and the consequences on these of smoking cessation. Smoking has also been reported to have beneficial effects on a wide range of medical conditions; the evidence has been reviewed by Baron. Here we focus solely on the potential benefits to the economy.

Government revenue from tobacco duty
Although strictly tobacco duty is a transfer payment rather than a true economic cost, it is a major source of government revenue and any reduction in smoking would involve a significant loss to the Exchequer. In 1994, 460 million cigarettes were consumed in the UK representing a spending of £10.917 million. Of this the government received duty of £8465 million (80% of retail price). This represents about 10% of total Customs and Excise revenue and 3% of total government direct and indirect tax revenue. Revenue from tobacco duty is considerably higher than the costs smoking imposes on society.

Employment in the tobacco and dependent industries
Employment in the UK in the tobacco industry has been falling over recent decades. The economic consequences of a further loss of jobs is commonly brought to society’s attention by the tobacco industry, and there are many other jobs which depend indirectly on smoking, including the retail and wholesale trade sectors. While reductions in smoking prevalence will reduce jobs in the tobacco industry, this will not necessarily lead to an overall increase in unemployment. Much of the money which smokers currently spend on cigarettes will be spent elsewhere, increasing the demand for other goods and services and affecting employment in these other industries. The extent of this effect depends on the spending patterns of former smokers. McNicoll and Boyle estimated that a complete cessation of cigarette purchasing by the citizens of Glasgow would bring net benefits to the Scottish economy. Each £1 million reduction in cigarette expenditure would lead to a net increase in Scottish output of £1.1 million and a net increase in Scottish employment of 64 jobs.

A similar result was found by Buck et al who estimated the effect of a 40% reduction in smoking—the target set by the 1992 UK policy document “The Health of the Nation.” Using a reasonable set of assumptions they estimated that the reduction in spending on tobacco would result in a net overall increase of 150,000 jobs in the UK.

Even in tobacco growing countries the consequent gain in jobs in other industries may exceed the loss experienced in the tobacco industry as tobacco consumption diminishes. In the USA Warner et al compared the south-east tobacco growing region with eight non-tobacco regions and estimated that, with no spending on tobacco, the south-east would lose 222,000 jobs but this would be compensated by a gain of 355,000 jobs throughout the rest of the country (assuming gov-
LEARNING POINTS

- Smokers impose costs on society for health services from smoking related diseases.
- Non-smokers live longer and thus impose higher costs on society in old age.
- Whether or not the short term health care cost savings from smoking cessation outweigh the long term extra costs of a larger elderly population depends on the chosen "discount rate".
- The cost of smoking to society includes much more than health care costs, and the cost of lost productivity at work from smoking related sickness absence is greater than the health care cost of smoking related illness.
- While cost saving is a benefit, the principal benefit of smoking cessation is the health gain associated with a longer living, healthier population.
- From a policy perspective, what matters is how cost effective are smoking cessation interventions compared with other preventive and curative interventions.

Cost to society of smoking cessation

The issue of discounting intangible benefits such as smokers depended on their use of low (or zero) discount rates. Rates above 4.5% (cf UK Treasury discount rate of 6%) produce the opposite result. Furthermore, the costs to society of smoking are considerably wider than those of health care addressed by the Barendregt study. This consequently underestimated the potential benefits of total smoking cessation.

Conclusions

The methodology of the Barendregt study was essentially sound. It accounted for all the main sources of smoking related health care costs but it was not fully comprehensive. The authors’ conclusion that the lifetime costs for non-smokers are higher than those for smokers depended on their use of low (or zero) discount rates. Rates above 4.5% (cf UK Treasury discount rate of 6%) produce the opposite result. Furthermore, the costs to society of smoking are considerably wider than those of health care addressed by the Barendregt study. This consequently underestimated the potential benefits of total smoking cessation.

From a policy perspective, however, none of this really matters much. What does matter is what can be done...
to reduce the costs to society of smoking—and at what cost? This involves the economic evaluation of smoking cessation policies, programmes, and interventions. Reviews of the cost effectiveness of smoking cessation measures suggest that, on economic grounds, further efforts to produce health gains through smoking cessation are fully justified.
