Prediction of pulmonary complications after a lobectomy in patients with non-small cell lung cancer

Abstract

Background—Although the preoperative prediction of pulmonary complications after lung major surgery has been reported in various papers, it still remains unclear.

Methods—Eighty nine patients with stage I–IIIA non-small cell lung cancer (NSCLC) who underwent a complete resection at our institute from 1994–8 were evaluated for the feasibility of making a preoperative prediction of pulmonary complications. All had either a predicted postoperative forced vital capacity (FVC) of >800 ml/m² or forced expiratory volume in one second (FEV₁) of >600 ml/m².

Results—Postoperative complications occurred in 37 patients (41.2%) but no patients died during the 30 day period after the operation. Pulmonary complications occurred in 20 patients (22.5%). Univariate analysis indicated that the factors significantly related to pulmonary complications were FVC <80%, serum lactate dehydrogenase (LDH) level ≥230 U/l, and arterial oxygen tension (Pao₂) <10.6 kPa (80 mm Hg). In a multivariate analysis the three independent predictors of pulmonary complications were serum LDH levels of >230 U/l (odds ratio (OR) 10.5, 95% CI 1.4 to 77.3), residual volume (RV)/total lung capacity (TLC) ≥30% (OR 6.0, 95% CI 1.1 to 33.7), and Pao₂ <10.6 kPa (OR 5.6, 95% CI 1.4 to 22.2).

Conclusions—The above findings indicate that three factors (serum LDH levels of >230 U/l, RV/TLC ≥30%, and Pao₂ <10.6 kPa) may be associated with pulmonary complications in patients undergoing a lobectomy for NSCLC, even though the patient group was relatively small for statistical analysis of such a diverse subject as pulmonary complications.

Keywords: non-small cell lung cancer; pulmonary complications; morbidity

Lung cancer is the leading cause of death among cancer patients. The necessity for surgical treatment is increasing because complete surgical removal of a tumour offers the best chance for a cure in patients with non-small cell lung cancer (NSCLC). A lobectomy remains the standard therapeutic option in most patients with early stage NSCLC. Although the operative mortality and morbidity following a lobectomy has decreased over the past decade, both factors still contribute significantly to the cost of treating such patients. Careful selection of the operative modalities is therefore required to reduce the overall mortality and morbidity.

Clinicians are often faced with the problem of morbidity, especially pulmonary complications, which tend to be impossible to predict. Pulmonary complications after lung resection can have serious consequences because the remaining lung tissue is severely compromised during the immediate postoperative period. In the present study we have reviewed a series of patients with NSCLC to evaluate the feasibility of preoperatively predicting pulmonary complications.

Methods

PATIENTS

From April 1994 to December 1998, 299 patients with primary lung cancer underwent lung resection at the Department of Surgery II, University of Occupational and Environmental Health, Kitakyushu, Japan. Of these, 89 patients with stage I–IIIA NSCLC in whom lobectomy was performed were assessed. All patients underwent the following diagnostic procedures preoperatively: brain computed tomographic (CT) scan, body CT scan, a pulmonary perfusion scintigraphic scan, and a bone scintigraphic scan. Spirometric tests were performed according to established guidelines. We calculated the predicted residual pulmonary function combined with xenon ventilation/perfusion scans from the ratio of right versus left fractional perfusion. The formula for the predicted residual pulmonary function is as follows:

Predicted residual pulmonary function = pulmonary function × (1—ratio of lung perfusion on the resected side × number of resected pulmonary segments/number of pulmonary segments on the resected side)

In our institution surgery is indicated in patients with a predicted postoperative forced vital capacity (FVC) of >800 ml/m² or forced expiratory volume in one second (FEV₁) of >600 ml/m². Routine systematic lymphadenectomy of hilar and mediastinal lymph nodes was performed in all cases. The charts were then retrospectively reviewed. The ineligibility factors are shown in table 1. The 19 variables listed in table 2 were evaluated.

POSTOPERATIVE COMPLICATIONS

The pulmonary complications included atelectasis and sputum retention requiring bron-
choscopic, pneumonia defined by radiographic infiltrates plus at least two of the following: temperature >37.7°C, white blood cell count >10 500/mm³, initiation of antibiotic therapy, an air leak requiring a thoracostomy tube drainage for more than seven days, bronchial asthma, chylothorax, and empyema. Cardiac complications included atrial fibrillation, bradycardia, and premature ventricular contractions, all of which required treatment. Other complications included liver dysfunction, gastric ulcer defined by endoscopy, depression, wound infection, and colitis, which all required treatment.

STATISTICAL ANALYSIS

The χ² test was used to examine the association between the incidence of complications and clinicopathological features. When the expected value was <5 the Fisher’s exact test was used. Variables with a p value of <0.3 were entered into the multivariate logistic regression program of the SAS. The cut off values were chosen to reflect extreme values over the normal range, or the clinical usefulness of these parameters. A p value of <0.05 was considered significant.

RESULTS

STUDY POPULATION

The mean (SD) age of the patients was 67.2 (8.6) years (range 42–85). There were 62 men and 27 women. Twenty four patients had squamous cell carcinoma, 60 had adenocarcinoma, three had large cell carcinoma, one had adenosquamous cell carcinoma, and one had large cell neuroendocrine carcinoma. According to the new international staging system for lung cancer following a complete systematic lymphadenectomy carried out in all patients, the staging was as follows: 43 patients were stage I, 26 were stage II, two were stage IIIA, six patients were stage IIIB, and 12 patients were stage IIIA. Pulmonary function tests showed a restrictive defect in five (5.6%), an obstructive defect in eight (9.0%), and a combined defect in three (3.4%).

COMPLICATIONS

All patients were extubated on the day of the operation. There were no deaths (operative mortality rate 0%) and re-operation was required in only one patient (1.1%) following empyema. No patient needed either mechanical ventilation or a tracheostomy. Overall, post-operative complications occurred in 37 patients (41.2%). Pulmonary complications occurred in 20 patients (22.5%). The postoperative complications and their incidence are shown in table 3.

PREDICTORS OF POSTOPERATIVE COMPLICATIONS

The univariate predictions of pulmonary complications including age, sex, history of smoking, serum total protein, serum albumin, %FEV₁, %FVC, FEV₁/FVC, hypercapnia, operative procedure, operated site, the existence of adhesions at operation, the pathological T and N stage, and the histological type were not predictive of pulmonary complications. FVC of <80%, serum LDH levels of ≥230 U/l, and arterial oxygen tension (Pao₂) of <10.6 kPa (80 mm Hg) were predictive of complications (table 4). In a multivariate analysis these three factors were found to be significant independent predictors of pulmonary complications (table 5).

Discussion

Advances in operative techniques and postoperative care have led to a further decline in the postoperative complication rates following a lobectomy with a mortality rate of 1–9% reported in recent studies.4,5 and morbidity occurring at an alarming rate of 11–47%.8–10 These mortality and morbidity data are generally obtained from eligible patients who are selected on the basis of their pulmonary function and other organ functions. We also selected surgical candidates on the basis of either a predicted postoperative FVC of >800 ml/m² or an FEV1 of >600 ml/m². The resulting 0% mortality suggests that our criteria appear to be generally acceptable. However, some morbidity still remains even in these selected patients. We therefore evaluated whether it is possible to predict pulmonary complications after a lobectomy because even patients eligible for surgery develop pulmonary complications.

Many investigators have tried to identify the factors that predict the occurrence of postoperative complications following a lobectomy. Previous studies have shown a relationship between perioperative pulmonary complications and preoperative variables including age,8–10 sex,9 obesity,11 chronic obstructive pulmonary disease,12,13 cigarette smoking,15 the measurement of maximum oxygen consumption during exercise,14 FEV1,8,9,15 predicted FEV1,15 and transfer factor (TLCO).16,17 However, these factors are not yet applicable at all institutions because the eligibility for surgery at each institution is different.

Our results suggest that the serum LDH level is strongly associated with postoperative morbidity. To our knowledge, only one report has shown a relationship between perioperative pulmonary complications and preoperative variables including age,8–10 sex,9 obesity,11 chronic obstructive pulmonary disease,12,13 cigarette smoking,15 the measurement of maximum oxygen consumption during exercise,14 FEV1,8,9,15 predicted FEV1,15 and transfer factor (TLCO).16,17 However, these factors are not yet applicable at all institutions because the eligibility for surgery at each institution is different.
