Exhaled nitric oxide and asthma: complex interactions between atopy, airway responsiveness, and symptoms in a community population of children

P J Franklin, S W Turner, P N Le Souëf, S M Stick

Background: Exhaled nitric oxide (FE\textsubscript{NO}) is raised in asthmatic children, but there are inconsistencies in the relationship between FE\textsubscript{NO} and characteristics of asthma, including atopy, increased airway responsiveness (AR), and airway inflammation. The aim of this study was to investigate the relationship between FE\textsubscript{NO} and asthma, atopy, and increased AR in children.

Methods: One hundred and fifty five children (79 boys) of mean age 11.5 years underwent an assessment that included FE\textsubscript{NO} measurements, spirometric tests, inhaled histamine challenge, and a skin prick test. Blood was collected for eosinophil count. Current and past asthma like symptoms were determined by questionnaire.

Results: In multiple linear regression analyses FE\textsubscript{NO} was associated with atopy (p < 0.001), level of AR (p = 0.005), blood eosinophil count (p = 0.007), and height (p = 0.002) but not with physician diagnosed asthma (p = 0.1) or reported wheeze in the last 12 months (p = 0.5). Separate regression models were conducted for atopic and non-atopic children and associations between FE\textsubscript{NO} and AR, blood eosinophils and height were only evident in atopic children. Exhaled NO was raised in children with a combination of atopy and increased AR independent of symptoms.

Conclusion: Raised FE\textsubscript{NO} seems to be associated with an underlying mechanism linking atopy and AR but not necessarily respiratory symptoms.

Subjects and protocol

Subjects were participants in a prospective birth cohort study of lung function, AR, and atopy that included data from probands and all family members enrolled from an unselected population. The probands had previously been assessed at 4 weeks, 6 months, 12 months, and 6 years of age. Data for the present study were gathered from the 11 year follow up study. Family members were studied in the first year and at the 6 and 11 year follow up surveys. In the present study 191 of the original cohort of 253 infants and 165 siblings were assessed. All children underwent an assessment that included spirometric tests, inhaled histamine challenge, skin prick testing, and blood eosinophil count. Current and past respiratory symptoms were assessed using a modified ATS questionnaire. Assessments took place either at the hospital or the child’s home. Exhaled NO was measured only in those attending hospital (n = 155, 97 of the original cohort; 58 siblings) and the results from these children are presented in this study. None of the children were symptomatic at the time of the study.

The study was approved by the medical ethics committee of Princess Margaret Hospital for Children. Informed consent was obtained from parents.

Exhaled nitric oxide

Exhaled NO was measured using a fast response chemiluminescence analyser (NOA 280, Sievers Instruments Inc, Boulder, CO, USA) as previously described.

were taken before spirometry and histamine challenge. Children maintained an expiratory flow of 35 ml/s and mouth pressure of 15 cm H₂O.

**Pulmonary function and airway responsiveness**

Pulmonary function testing was performed using a hand held spirometer (Pneumocheck Spirometer 6100; Welch-Allyn, Skaneateles Falls, NY, USA) in accordance with published guidelines.³⁷ Airway responsiveness to histamine was determined using the rapid dosimeter technique.³⁷ Responsiveness was expressed as the dose of histamine (µM) that provoked at least a 20% fall in FEV₁ (PD₂₀) and increased AR was defined as PD₂₀ <7.8 µM histamine.²³ A dose response slope (DRS) was also calculated using the method of O’Connor et al.²³

**Skin prick testing and eosinophil count**

Skin reactivity to cow’s milk, egg white, rye grass, mixed grass, Dermatophagoides farinae, Dermatophagoides pteronyssinus, cat dander, dog dander, Alternaria alternans and Aspergillus fumigatus (Hollister-Stier, Elkhart, IN, USA) was assessed by skin prick tests as described by Pepys.²³ The positive control (Hollister-Stier, Elkhart, IN, USA) was assessed by skin prick tests and Alternaria alternans (Hollister-Stier, Elkhart, IN, USA) in accordance with published guidelines.¹⁹ Airway responsiveness to histamine was determined using the rapid dosimeter technique.²³

**Exhaled NO concentrations**

Exhaled NO concentrations were measured in 155 subjects (79 boys) of mean (SD) age 11.5 (2.3) years (range 6–18).

**RESULTS**

Exhaled NO concentrations were measured in 155 subjects (79 boys) of mean (SD) age 11.5 (2.3) years (range 6–18). There was no significant difference with regard to age, sex, height, atopic status, AR, FEV₁, eosinophil count, physician diagnosed asthma, reported recent wheeze, and use of inhaled steroids between these children and those in whom FENO measurements were not made (n = 201).

Five children treated with regular inhaled corticosteroids (ICS) were excluded from analyses because of the known effects of ICS on FENO. Of the remaining 150 children, spirometric tests were performed in all individuals, skin prick testing in 149 (99%), bronchial challenge in 144 (96%), and eosinophil counts in 136 (91%). Eighty three children (56%) were atopic, 54 (38%) had increased AR, 34 (23%) reported wheeze in the past 12 months, and 26 (17%) had physician diagnosed asthma.

In univariate analyses, FENO was higher in children who had reported physician diagnosed asthma (16.4 ppb, 95% CI 11.0 to 24.6) than in non-asthmatic children (11.0 ppb, 95% CI 9.4 to 12.9; p < 0.03), in those with reported recent wheeze (16.6 ppb, 95% CI 11.9 to 23.2) than in those without recent wheeze (10.8 ppb, 95% CI 9.2 to 12.7; p = 0.01), and in those with current asthma (24.5 ppb, 95% CI 15.0 to 40.0) than in those without current asthma (11.0 ppb, 95% CI 9.5 to 12.8; p < 0.001). Atopic children (17.9 ppb, 95% CI 14.9 to 21.4) had significantly higher FENO levels than non-atopic children (7.2 ppb, 95% CI 6.0 to 8.7; p < 0.001) and there was a positive correlation between the number of skin prick reactions and FENO (Pearson’s correlation coefficient r = 0.61, p < 0.001). There was a positive association between FENO and DRS (r² = 0.21, p < 0.001), eosinophil count (r² = 0.11, p < 0.001), and height (r² = 0.05, p < 0.008). There were no associations between FENO and measurements of pulmonary function when adjusted for height. The relationship between FENO and DRS in atopic and non-atopic children is shown in fig 1.

In the multiple regression model atopy (p < 0.001), FENO (p = 0.003), DRS (p = 0.003), eosinophil count (p = 0.008), and height (p = 0.032) were all significantly associated with FENO (table 1). Neither physician diagnosed asthma (p = 0.1) nor recent wheeze (p = 0.5) were associated with FENO in this model. There was a significant interaction between atopy and DRS (p = 0.001) and a trend for an interaction between atopy and eosinophil count (p = 0.06). In order to examine these interactions further, separate regression models were constructed for atopic and non-atopic children. In these models DRS, eosinophils, and height were associated with FENO in atopic (table 2) but not in non-atopic children (table 3). Again, neither physician diagnosed asthma nor recent wheeze were associated with FENO in either of these models.

![Figure 1](http://thorax.bmj.com)
As there were a number of sibling pairs in this cohort, there may be genetic linkage within the group. The children from the original cohort (n = 97) were therefore analysed separately and the observed associations persisted.

**DISCUSSION**

This study has shown that atopy modifies the association between FE NO and positive skin prick reactions in healthy children. We have previously reported an association between raised FE NO and positive skin prick reactions in healthy children.

The association between increased FE NO and atopy in healthy subjects has been confirmed in other studies, but it is not a universal finding. Similarly, the data regarding the association between FE NO and AR have been inconclusive. The results of this study extend our earlier observations and help to explain some inconsistencies in reported data. Our observations also explain the consistent reports of raised FE NO levels in atopic compared with non-atopic asthmatics.

A major finding from both our study and a recent study by Steerenberg et al is that the relationship between FE NO and AR is only evident in atopic children. Ludviksdottir and colleagues reported a similar relationship in asthmatic adults. There is a well established relationship between atopy and increased AR in both children and adults, and our data suggest that increased NO production in the airways may be associated with a mechanism linking these two factors. This may involve inflammatory processes and would support the hypothesis that FE NO is a marker of allergic airway inflammation. Peat et al suggested that IgE mediated inflammatory reactions in the airways of atopic children could lead to increased AR. We found that there was a relationship between FE NO and blood eosinophils which was also dependent on the presence of atopy. This relationship has also been reported in an unselected population of children, as well as in a group of asthmatic children. In our study there was a positive correlation between peripheral eosinophils and DRS in the atopic but not the non-atopic children (data not shown). Blood eosinophils, however, do not necessarily reflect inflammatory processes in the lungs, and an alternative explanation is that increased FE NO in this phenotype may be due to genetic variations in NO synthase (NOS) genes. In patients with asthma and cystic fibrosis, variations in FE NO are associated with a polymorphism in the NOS1 gene. The NOS1 isoform has been shown to be important in the regulation of AR in animal models. Further investigations are required to determine the contribution of the various NOS isoform(s) to NO production in the airways of children with atopy and increased AR.

Interestingly, we found that the association between FE NO and atopy and increased AR was independent of symptoms. This was a representative population sample of asthmatic children, although children with more severe asthma (those taking ICS) were excluded because of the known effects of ICS on FE NO. Our findings are in agreement with those of Leuppi et al who found significantly raised FE NO levels in

atopic children with increased AR, regardless of symptoms. These authors suggested that FE(NO) may be more closely associated with increased AR than symptoms. In contrast, Henriksen et al\textsuperscript{10} found that suspected asthmatic adolescents with both atopy and increased AR had higher FE(NO) levels than healthy subjects with a similar phenotype. Similarly, Steerenberg et al\textsuperscript{11} found that FE(NO) was associated with respiratory symptoms in atopic children, but it appears that these authors might not have controlled for AR when investigating the association between FE(NO) and symptoms. Our results, if confirmed in future studies, suggest that raised FE(NO) levels in children are associated with a common asthma phenotype (that is, atopy and increased AR) but not with asthma per se.

Our observation that FE(NO) is raised in healthy children with both atopy and increased AR raises an intriguing possibility that NO might be protective in these children who are at risk of asthma but who have not developed symptoms. Indeed, there have been suggestions that NO may have a bronchoprotective role through its actions on smooth muscle relaxation and inhibition of smooth muscle proliferation.\textsuperscript{15} Alternatively, raised FE(NO) may identify children who have latent asthma and are at risk of developing symptoms. Both atopy and increased AR in childhood have been reported as risk factors for the subsequent development of asthma in early adulthood.\textsuperscript{26} However, atopy and increased AR can coexist in adults in the absence of symptoms.\textsuperscript{27} The association between raised FE(NO) levels and the development of asthma later in life can only be addressed by longitudinal data. This cohort will be reassessed 5 years after the present data were obtained.

There has been considerable interest in FE(NO) as a diagnostic tool for asthma. A number of studies have reported good sensitivity and specificity of raised FE(NO) for discriminating between asthmatics and non-asthmatics.\textsuperscript{20-22} In each of these studies the asthmatic patients had increased AR or significant airways reversibility while the non-asthmatics all responded normally. No study has investigated the diagnostic value of FE(NO) in an unselected population. On the basis of our results we propose that low levels of FE(NO) may be useful to exclude increased AR in atopic children with symptoms and, therefore, to help to exclude a diagnosis of asthma. Increased AR is almost ubiquitous in clinically obvious asthma and most asthmatic children are atopic.\textsuperscript{21} Tests of AR are not feasible in most clinical situations, particularly in children. Our data suggest that atopic children with respiratory symptoms but low FE(NO) levels are unlikely to have increased AR. Indeed, in our study, if FE(NO) levels are less than 18.4 ppb, the likelihood ratio for atopic children to have increased AR is only 0.23. We suggest that the diagnostic value of low FE(NO) levels could be further tested in a prospective study.

We have used an expiratory flow rate of 35 ml/s for measuring FE(NO). The study was started before publication of recommendations for the measurement of FE(NO) in children.\textsuperscript{32} However, the marginally lower expiratory flow rate than that suggested in these guidelines used in our study is unlikely to affect our findings since Kissoon et al\textsuperscript{33} have reported that flow rates between 30 and 50 ml/s are appropriate for children. Indeed, the use of a low flow rate may have increased our ability to measure differences in FE(NO) between groups. Deykin et al\textsuperscript{34} showed in adults using higher flow rates that the discriminatory power of FE(NO) for differentiating between asthmatic and non-asthmatic subjects was not affected by expiratory flow rates ranging from 47 ml/s to 500 ml/s.

In summary, we have shown that atopy is important in the relationship between FE(NO) and AR. In this study, FE(NO) was associated with increased AR only in atopic children. Furthermore, there was an association between FE(NO) and blood eosinophils that was also only evident in atopic children. This supports the concept that FE(NO) reflects allergic airway inflammation and this may be one of the mechanisms explaining the relationship between atopy and AR. Alternatively, raised FE(NO) levels in children with both atopy and increased AR may be due to variations in NOS genes. This needs to be explored further. Raised FE(NO) levels in non-asthmatic atopic children with increased AR may either be predictive for the development of asthma or may indicate a protective role of NO against the development of symptoms. These issues will be addressed in the next follow up study of this population of children. After controlling for both atopy and increased AR, we were unable to show an association between FE(NO) and asthma or asthma like symptoms. This suggests that raised FE(NO) levels in children are associated with a common asthma phenotype but not with asthma per se. These results have implications for the use of FE(NO) as a diagnostic tool for asthma. However, we have proposed a role for FE(NO) in atopic children with symptoms of unknown aetiology to exclude increased AR and, by inference, to help to exclude asthma.
