Inhaled corticosteroids and mortality in chronic obstructive pulmonary disease

Background: Clinical studies suggest that inhaled corticosteroids reduce exacerbations and improve health status in chronic obstructive pulmonary disease (COPD). However, their effect on mortality is unknown.

Methods: A pooled analysis, based on intention to treat, of individual patient data from seven randomised trials (involving 5085 patients) was performed in which the effects of inhaled corticosteroids and placebo were compared over at least 12 months in patients with stable COPD. The end point was all-cause mortality.

Results: Overall, 4% of the participants died during a mean follow up period of 26 months. Inhaled corticosteroids reduced all-cause mortality by about 25% relative to placebo. Stratification by individual trials and adjustments for age, sex, baseline post-bronchodilator percentage predicted forced expiratory volume in 1 second, smoking status, and body mass index did not materially change the results (adjusted hazard ratio (HR) 0.73; 95% confidence interval (CI) 0.55 to 0.96). Although there was considerable overlap between subgroups in terms of effect sizes, the beneficial effect was especially noticeable in women (adjusted HR 0.46; 95% CI 0.24 to 0.91) and former smokers (adjusted HR 0.60; 95% CI 0.39 to 0.93).

Conclusions: Inhaled corticosteroids reduce all-cause mortality in COPD. Further studies are required to determine whether the survival benefits persist beyond 2–3 years.

METHODS
Studies included: design and treatment

The Inhaled Steroid Effects Evaluation in COPD (ISEEC) study included patient level data from all clinical trials in which patients with stable COPD were randomly assigned to inhaled corticosteroids or placebo for at least 12 months. These trials included the Lung Health Study-2 (LHS-2),13 Copenhagen City Lung Study (CCLS),14 Inhaled Steroids in Obstructive Lung Disease in Europe (ISOLDE),16 European Respiratory Society Study on Chronic Obstructive Pulmonary Disease (EUROSCOP),17 Trial of Inhaled Steroids And long acting P2 agonists (TRISTAN),18 and trials by Szafranski et al17 and Calverley et al.14 The full details of the individual trials have been published elsewhere.12–18

Participants in these trials were routinely seen at least every 3–6 months by study investigators. Mortality information was collected and collated by study personnel and recorded in the trial databases. Anonymised data collected

† Deceased.
from the seven individual trials were sent from each trial site to the central ISEEC coordinating centre where they were merged together for analytical purposes. We applied Hankinson’s prediction equation to calculate percentage predicted forced expiratory volume in 1 second (FEV1) across all studies. Principal causes of death were classified on reports by study investigators and were categorised into four groups: cardiovascular, respiratory, cancer, and others/unknown.

### Statistical analysis

For the primary analysis we compared the efficacy of inhaled corticosteroids on all-cause mortality rates based on the original allocation of participants in the individual trials, regardless of whether they did or did not have complete follow up. This end point was chosen a priori. The participants in each trial were followed from the date of enrolment to the date of withdrawal (for whatever reason), death or study completion, whichever came first. In ISOLDE, complete mortality data were obtained on all study participants for 3 years through the UK Office of Population Statistics registry. In LHS-2, mortality status was established by the investigators for study participants over the duration of the trial. For the other studies, complete mortality data were obtained on those who completed the trials. Deaths that occurred after the withdrawal date were not ascertained except among those who developed a serious adverse event during the trial period and died before the full resolution of the serious adverse event had occurred.

Kaplan-Meier curves were generated to compare the time to death between the steroid and placebo arms, and the log-rank statistic determined the significance of differences between the curves. Cox proportional hazards regression modeling was used to estimate the relative effect of inhaled corticosteroids on all-cause mortality according to confounding variables. Hazard ratios (HR) and the nominal 95% confidence intervals (CI) were presented. We checked for the proportional hazards assumption visually and by including a time-interaction term to the model and the assumption was met (p = 0.741). In the adjusted model we stratified by individual trials which allowed hazard functions to differ for each trial. The model also controlled for age (in quintiles), sex, baseline post-bronchodilator percentage predicted FEV1 (in quintiles), baseline smoking status, and body mass index (BMI; in quintiles) of the trial participants. Secondary analyses included subgroup analyses based on sex, baseline smoking status, and above and below median values for age, baseline FEV1, and BMI. Competing risk models were used to evaluate the hazards of cause-specific mortality. All tests were two tailed in nature and were conducted using SAS 8.2 software (Cary, NC). Continuous variables are shown as mean (SD) unless otherwise indicated.

### RESULTS

The characteristics of the trials included in the ISEEC are summarised in table 1. In total, data from 5085 participants were analysed. None of the participants (including those who withdrew prematurely) was excluded from the analysis. The baseline characteristics of the trial participants are summarised in table 2. The mean (SD) age of the participants was 59.0 (9.3) years and the mean post-bronchodilator FEV1 was 58.4 (19.5)% of predicted. Nine percent of the cohort (N = 436) were in the Global Initiative for Chronic Obstructive Lung Disease (GOLD)1 class 4 (FEV1 <30% of predicted); 28% (N = 1419) were in GOLD class 3 (FEV1 30–49% of predicted); 49% (N = 2466) were in GOLD class 2 (FEV1 50–79% of predicted); and 15% (N = 764) were in GOLD class 1 (FEV1 ≥80% of predicted). The mean bronchodilator response was 9 (12)% (0.13 (0.15) l) from pre-bronchodilator values. 71% of the participants were men and 69% were current smokers at the time of enrolment. In total, 973 participants (12%) withdrew prematurely from EUROSCOP, TRISTAN, and trials by Szafranski and Calverley and, as such, their vital status beyond the date of the study withdrawal could not be determined. In these trials, more participants withdrew prematurely from the placebo than from the steroid arm (21% in placebo versus 18% in the steroid arm; p = 0.006). The mean length of follow up was 26 (15) months; this was similar in the placebo and steroid arms of the trials.

Overall, 201 (4.0%) of the participants died during the trial period. Those who died during follow up were older (64

Continuous variables are presented as mean (SD) and dichotomous variables as percentage of participants in each individual trial.
(7) years v 58 (9) years; p<0.001) and had lower post-bronchodilator FEV1 (48% (17%) v 59% (19%); p<0.001) at the time of randomisation than those who survived to the end of the study period. Male participants were more likely to die than female participants (4.5% v 2.6%; p = 0.002). The baseline BMI was similar between those who did and did not die during follow up (25 (5) kg/m² v 25 (5) kg/m²; p = 0.794).

Compared with placebo, participants assigned to inhaled corticosteroids had a lower risk of mortality (HR 0.75; 95% CI 0.794). Stratification by individual trials and adjustments for age, sex, baseline post-bronchodilator percentage predicted FEV1, baseline smoking status, and BMI did not materially change the results (adjusted HR 0.73; 95% CI 0.55 to 0.96).

The effects of inhaled corticosteroids in the various subgroups are summarised in table 3. The beneficial effect of inhaled corticosteroids was especially noticeable in women (adjusted HR 0.46; 95% CI 0.24 to 0.91), former smokers (adjusted HR 0.60; 95% CI 0.39 to 0.93), and in those whose baseline post-bronchodilator FEV1 was below 60% of predicted (adjusted HR 0.67; 95% CI 0.48 to 0.94). We chose this FEV1 cut off because it was the median FEV1 value. None of the interaction terms was significant at the p<0.05 level.

Subgroup analyses based on GOLD severity classes showed that, in participants in GOLD classes 3 and 4, inhaled corticosteroids reduced mortality (adjusted HR 0.66; 95% CI 0.45 to 0.96). The effect was non-significant among patients in GOLD class 1 (adjusted HR 0.84; 95% CI 0.19 to 3.65) and 2 (adjusted HR 0.79; 95% CI 0.51 to 1.23). The effects of inhaled corticosteroids were similar between fluticasone, budesonide and triamcinolone, although the width of the confidence intervals were different, reflecting the different sizes of the trials. We also performed subgroup analyses in which trials with a follow up time of 12 months or less were excluded. The results were similar whether trials were included or excluded in those with FEV1 <60% of predicted. In such patients, the exclusion of these three studies resulted in an HR of 0.67 (95% CI 0.47 to 0.95). There was no significant heterogeneity in the HRs across the trials (p value for test of heterogeneity 0.93; fig 2).

The principal causes of death are summarised in table 4, grouped into four major categories as described above. Most of the deaths were cardiorespiratory in nature (64% of all deaths). Approximately 21% of the deaths were from cancer. Of the 42 cases of carcinoma related deaths, 79% were attributed to lung cancer (N = 33). Other causes of death (including sudden deaths) and unknown causes accounted for the remaining 15% of deaths. Because of the small number of deaths in each category, none of the comparisons was significant at the p<0.05 level.

**DISCUSSION**

The most important and novel finding of this study is that treatment with inhaled corticosteroids is associated with a 27% reduction in all-cause mortality in individuals with stable COPD. The beneficial effects of these medications appear to be especially pronounced in women (adjusted HR 0.46) and former smokers (adjusted HR 0.60). However, none of the interaction terms was significant so the survival data in the various subgroups should be interpreted cautiously.

This study has some limitations. Firstly, none of the primary studies included in the pooled analysis was designed to evaluate mortality as an end point, which imposed certain restrictions to the pooled analysis. For instance, five of the seven trials included in this pooled analysis did not ascertain mortality information on participants who withdrew prematurely from the trials. In these trials, participants were followed up to the date of withdrawal and any deaths occurring after this date were not recorded in the trial databases, except for those decedents who withdrew initially because of a serious adverse event from the study medication or placebo. As such, those who withdrew prematurely in these trials were recorded as “alive” at the final date of their assessment and any subsequent follow up period they were recorded as “missing.” Data from the ISOLDE trial indicate that the placebo group is more likely to withdraw prematurely than the steroid group (53% v 44%; p = 0.008), and mortality is much more likely in those who withdrew prematurely than in those who remain in the trial (p<0.001). It is therefore likely that, by not fully capturing deaths which occurred in the post-withdrawal period, we may have underestimated the true effect of inhaled corticosteroids because the rate of withdrawals was higher in the

FEV₁, forced expiratory volume in 1 second; ICS, inhaled corticosteroids.
mortality. Inhaled corticosteroids also have a small effect on attenuating airway hyperresponsiveness, which is found in 60–80% of patients with mild to moderate COPD. Increased airway hyperresponsiveness has been linked to increased COPD mortality. Interestingly, airway hyperresponsiveness is more common in women than in men with COPD. The relative importance of these potential mechanisms requires further exploration.

This study was underpowered to evaluate the effects of inhaled corticosteroids on specific causes of mortality. However, there was a trend towards a lower risk of cancer related mortality for those randomised to inhaled corticosteroids. Whether or not this is a real effect will require further study. Chronic inflammation has been implicated in the development of malignant diseases. In particular, cyclooxygenase (COX)-2 enzymatic activities may regulate immune responses that promote tumor growth. Inhaled corticosteroids over 6 months have been shown to reduce prostaglandin E2 levels, a product of COX-2 pathways, and to downregulate proto-oncogene (for example, BCL2) expression needed to address these issues in patients with COPD.

Intriguingly, inhaled corticosteroids may be more effective in former than in current smokers. This pattern has also been observed in asthma. Acutely in COPD, smokers have a lower therapeutic response to oral corticosteroids than former smokers. It has been postulated that smoking induces a state of relative steroid resistance by increasing oxidative stress and by upregulating production of various pro-inflammatory cytokines including interleukin-6 (IL-6), IL-8, IL-1β, and monocyte chemoattractant protein-1. Additionally, cigarette smoke appears to reduce histone deacetylase activity and its expression in alveolar macrophages, making these cells relatively resistant to corticosteroids since one of the principal targets of corticosteroid action is by switching off gene expression of inflammatory genes through the recruitment of histone deacetylases. Consistent with these findings, our data suggest that, for patients with COPD to experience maximal benefit from inhaled corticosteroids, cessation of smoking is of prime importance. Because the individual trials included in the current pooled analysis were originally designed and conducted at a time when anti-inflammatory drugs were thought to be most helpful in smokers with COPD, trials generally oversampled the smoking subpopulation of COPD patients. This may have attenuated (or even negated) the beneficial effects of inhaled corticosteroids observed in these studies.

In summary, the present pooled analysis indicates that inhaled corticosteroids are likely to be effective in reducing all-cause mortality in stable COPD. Further research is needed to understand better the molecular and physiological mechanisms by which inhaled corticosteroids reduce mortality in COPD.

ACKNOWLEDGEMENT

The authors dedicate this paper to the fond memory of their loving friend and colleague, Professor Romain Pauwels.
