LETTERS TO THE EDITOR

If you have a burning desire to respond to a paper published in Thorax, why not make use of our "rapid response" option? Log on to our website (www.thoraxjnl.com), find the paper that interests you, and send your response via email by clicking on the "ellettori" option in the box at the top right hand corner.

Providing it isn't libellous or obscene, it will be posted within seven days. You can retrieve it by clicking on "read ellettori" on our homepage.

The editors will decide as before whether to also publish it in a future paper issue.

COPD, restrictive syndrome and inflammation

In a recent issue of Thorax Gan et al.1 published a systematic review and meta-analysis of 14 reports which confirmed the strong association between COPD and biological markers of systemic inflammation. In six reports COPD was diagnosed by the presence of a ratio of forced expiratory volume in 1 second to forced vital capacity (FEV1/FVC) ratio lower than 0.7. However, in the remaining eight studies this measure was not available, and the authors assumed that all participants in the lowest quartile of FEV1/FVC (and, in one study, of FVC%) had a diagnosis of COPD. In these cases the corresponding highest quartile group served as control. Since a COPD diagnosis based on a decreased FEV1/FVC ratio was lacking in eight reports, the possibility cannot be excluded that a certain number of patients included in the meta-analysis did not have COPD but, rather, a restrictive ventilatory defect. This could be particularly true for participants in the study by Engstrom et al.2 who were characterised only by a low FVC.

According to the current GOLD guidelines,3 only an FEV1/FVC ratio lower than 0.7 indicates airflow obstruction, thus allowing a COPD diagnosis. Indeed, in the absence of particular pulmonary diseases, many subjects show a homogenous decrease in all dynamic lung volumes (FEV1, FVC, PEF) without any change in the FEV1/FVC ratio, and are thus considered to have “impaired lung function”. The occurrence of respiratory symptoms, systemic inflammation, and the increased risk of cardiovascular disease are the only features that subjects with restrictive disease share with COPD. In fact, whereas COPD is characterised by a decrease in body mass index and blood lipids, subjects with restrictive disease often have abdominal obesity, insulin resistance, and other metabolic risk factors.

Although we believe that most of the included patients were affected by COPD, the possible inclusion of patients with restrictive lung disease may have altered the statistical conclusions of the meta-analysis. In addition, the decision to select patients in whom the ratio of FEV1 to forced vital capacity (FVC) limits in defining COPD are bound to relying on arbitrary cut off values for large population based studies, it is reasonable (and useful) to compare the outcome of interest—in this case, systemic inflammation—between extremes of FEV1 (that is, worst FEV1, quartile to best quartile group). This method avoids imposing any arbitrary constraints in the definition of COPD and allows maximal utilisation of the data points. However, a potential limitation of this approach is the possibility of diagnostic misclassification between restrictive and obstructive lung diseases. To specifically address this concern, we excluded population based studies in which a FEV1/FVC ratio was not used to define COPD4,5 and reanalysed the C-reactive protein (CRP) and fibrinogen data. Even after the exclusion of these studies, the standardised mean difference between COPD and control subjects was 0.48 units (95% confidence interval (CI) 0.38 to 0.98) or 4.85 mg/l (95% CI 1.92 to 7.78). For the fibrinogen data, the standardised mean difference between COPD and control subjects was 0.48 units (95% CI 0.43 to 0.54) or 0.42 g/l (95% CI 0.00 to 0.84). These results indicate that the possible contamination of individuals with restrictive defects in the groups with low FEV1, or FVC did not influence the overall findings. Finally, we did not include data from one of our previous reports6 because the study sample was taken from the same source population as the study by Mannino and colleagues7 which was included in the meta-analysis.

Authors’ reply
We wish to thank Dr Fimognari and colleagues for highlighting the difficult issue of defining chronic obstructive pulmonary disease (COPD). In most circumstances a spirometric cut off is used to define COPD, but there is no uniform consensus on what should be and different expert panels have promulgated different spirometric cut off values.4,8 COPD is a disease characterised by lung inflammation and patient symptoms (most notably dyspnoea). Studies have shown that the relationship between airflow inflammation and patient symptoms with forced expiratory volume in 1 second (FEV1) is a continuum and is not threshold dependent.9 Thus, any attempts to impose FEV1 or the ratio of FEV1 to forced vital capacity (FVC) limits in defining COPD are bound to be arbitrary and contentious. Rather than

7 Mendlall MA, Strachan DP, Butland BK, et al. C-reactive protein: relation to total mortality,
TB screening and anti-TNFα treatment

Reactivation of tuberculosis (TB) is a major concern during treatment with TNF inhibitors. Different guidelines to detect active and latent TB have been recommended in various countries before starting treatment with these drugs. There is evidence that their application has led to a significant reduction in the number of cases of TB, but we do not know which is the most cost effective strategy.

In our department 69 consecutive patients with rheumatoid arthritis (n = 53), ankylosing spondylitis (n = 12), and psoriatic arthritis (n = 6) considered for treatment with TNF inhibitors have recently been screened for TB infection according to the Italian guidelines. All underwent a careful history, tuberculin skin testing by intradermal injection of 0.2 ml 10 TU PPD (Mantoux method), and chest radiography. In order to enhance the sensitivity of tuberculin testing we had stopped steroid treatment in all patients at least 1 week before performing the test. Patients were considered to be affected by latent TB if they had any of the following conditions: (1) unequivocal history of previous TB; (2) positive tuberculin reaction (at least 5 mm skin induration at 72 hours); (3) radiographic lesions consistent with old TB (calcified nodular lesions, apical fibrosis, pleural scar, ring). According to our guidelines, patients with latent TB undergoing treatment with TNF inhibitors receive preventive chemotherapy.

Our patients were predominantly women (63.8%) with a mean age of 55.8 years (range 21–81). We found a history of previous TB in (63.8%) with a mean age of 55.8 years (range). According to our guidelines, patients with latent TB undergoing treatment with TNF inhibitors receive preventive chemotherapy.

Risedronate induced BOOP complicated with sarcoidosis

Bisphosphonates are synthetic compounds that are taken up preferentially by skeletal tissue and suppress osteoclast mediated bone resorption. They are being used increasingly in the treatment of osteoporosis. Broncho-constriction caused by bisphosphonates has been described but drug induced pneumoni has not previously been reported. This is the first report of interstitial pneumonia induced by the bisphosphonate risedronate.

A woman developed an intramuscular mass in her right arm at the age of 51 years. Sarcoidosis was diagnosed by non-necrotising sarcoid granulomas in the resected specimens of the mass, bilateral hilar lymphadenopathy on the chest radiograph, a negative reaction to tuberculin test, and an increase in the serum angiotensin converting enzyme (ACE) level to 27.9 U/ml. She had pain in her right arm due to the mass and was treated with prednisolone for 10 years. The mass disappeared and the ACE level fell to 9.6 U/ml. Two months later she developed a dry cough, high fever, and bilateral infiltrative shadows were seen on the chest radiograph (fig 1A). A high resolution CT scan showed multiple consolidation and ground glass opacity with interlobular and intralobular interstitial thickening (fig 1B). Mediastinal lymph nodes measuring about 1 cm and small amounts of bilateral pleural effusion were visible on the CT scan. Chest auscultation showed no crackles and neither the superficial lymph nodes nor the intramuscular mass lesions were palpable. Laboratory examination showed white blood cell (WBC) count of 9100/μl, C-reactive protein (CRP) 7.31 mg/dl, lactate dehydrogenase (LDH) 201 U/ml, ACE 5.3 U/ml, and lysozyme 8.9 U/ml. Total cell count of the bronchoalveolar lavage (BAL) fluid performed on left B2 was 4.18×10^7 with 43.4% macrophages, 15.8% neutrophils, 24.2% lymphocytes, and 16.0% eosinophils. The CD4+/CD8+ ratio of lymphocytes in the BAL fluid was 1.37. No pathogenic organisms were detected in the BAL fluid, and transbronchial lung biopsy specimens revealed no granulomas but cellular alveolitis with intraluminal polymold organisation consistent with bronchiolitis obliterans organizing pneumonia (BOOP). These findings ruled out reactivation of sarcoidosis.

Treatment with several antibiotics did not improve her symptoms and laboratory findings, so all her drugs (risedronate, prednisolone, metformin, and sazic-to) were stopped because drug induced pneumoni was suspected. Her high fever began to resolve about 5 days after stopping the drugs and her symptoms and the abnormal shadows on the chest radiograph disappeared 2 weeks later. The WBC and CRP level were also normalised. A drug lymphocyte stimulation test (DLST) on her peripheral lymphocytes gave a positive reaction only to risedronate with a stimulation index of 265%. There was a negative reaction to the other four drugs, all of which had been administered to her for at least 4 years. She was therefore diagnosed with risedronate induced pneumoni.

Amino-bisphosphonates including alendronate, pamidronate, and risedronate are reported to induce pro-inflammatory cytokines from macrophages in vitro and in vivo.

and to cause transient pyrexia, a flu-like syndrome, and serological changes resembling a typical acute phase reaction in some cases. They are also reported to induce anterior uveitis through these reactions or specific immunological responses. However, pneumonitis associated with amino-bisphosphonates has not been previously reported. In this case the specific immunological reaction to risedronate by DLST suggested that her lung disease was caused by the drug rather than by non-specific release of pro-inflammatory cytokines.

Osteoporosis is a common disease and bisphosphonates will be prescribed frequently. The possibility of pneumonitis caused by risedronate and other bisphosphonates needs to be kept in mind.

Bacterial denitrification, nitric oxide and aerial pH in CF

The recent findings of Ojoo et al are of considerable interest. However, one confounding factor that appears to have been overlooked in recent studies of aerial pH and exhaled breath nitric oxide (eNO) levels in cystic fibrosis (CF) is that of bacterial respiration. Pseudomonas aeruginosa adopts an anaerobic and biofilm mode of existence within the CF lung and, under such environmental conditions, it uses NO rather than oxygen as an electron donor to generate energy via oxidative phosphorylation. This bacterial denitrification results in the stepwise reduction of oxides of nitrogen to nitrite (NO2) and nitrate (NO3). The NO2/NO3 ratio in exhaled breath condensate (EBC) was also lower in subjects with CF.

d to change the chemical composition of the lung microenvironment in CF.

Authors’ reply

We thank Dr Reid for his interest in our paper. Bacterial denitrification involves the stepwise reduction of oxides of nitrogen to nitrite and nitrate, and support oxidative phosphorylation. Gaston et al have previously proposed that consumption of nitric oxide (NO) during this process might be one factor contributing to the low fractional exhaled NO concentration (FeNO) seen in cystic fibrosis (CF). It is clearly not the only mechanism, however, as decreased FeNO levels have been reported in infants with newly diagnosed CF, and reduced NO generation is also described in cystic fibrosis transmembrane conductance regulator (CFTR) deficient mice. Bacterial denitrification would be expected also to deplete nitrate (NO3) and nitrite (NO2) levels in the local milieu and to increase its pH.

In our study 14 of the 18 subjects with stable CF were chronically colonised with Pseudomonas aeruginosa. Interestingly, FeNO levels were indeed significantly lower in CF subjects with P aeruginosa than in those without (2 (1) vs 5 (7) ppb; p = 0.015). The median NO2/NO3, NO2, and NO3 levels in exhaled breath condensate (EBC) were also lower in subjects with P aeruginosa, although this difference did not reach statistical significance. Irrespective of the presence of P aeruginosa, values for both NO2 and NO3/NO2 were substantially higher in CF subjects than in healthy controls. There was little difference in the median pH of the EBC between CF subjects with and without P aeruginosa.

These further analyses provide support for the suggestion that denitrification by P aeruginosa may modulate the nitrogen redox balance in CF airways. They are consistent with the findings of Gaston et al who described a mild respiratory distress in newly identified cases of P aeruginosa in vitro and also a reduction in NO3 levels in the sputum of CF subjects after antipseudomonal treatment. Further comparisons involving larger numbers of CF subjects with and without P aeruginosa, and investigation of the relative impact of antimicrobial therapies in the two groups, may help to define the extent to which this mechanism operates in CF airways in vivo. Its relevance to airway pathophysiology, however, will be more difficult to determine.

Exhaled NO in diffuse alveolar haemorrhage

The syndrome of diffuse alveolar haemorrhage (DAH) is associated with a wide variety of diseases. Haemoptysis, falling haemoglobin, and air space opacities on the chest radiograph constitute the triad of features suggestive of DAH which should be confirmed by bronchoalveolar lavage (BAL). However, haemoptysis can be absent in up to one third of patients. A sensitive marker of DAH is a sequential increase in the carbon monoxide lung transfer factor (Tco). This results from the increased availability of haemoglobin within the alveolar compartment which avidly bonds carbon monoxide.

Although informative, the Tco often cannot be measured in patients with DAH as they might be too ill. Nitric oxide (NO) combines with haemoglobin much faster than carbon monoxide and is continuously produced in the respiratory tract. Exhaled NO can be measured either online or offline even in acutely ill patients by collection of exhalate in a bag for subsequent analysis. We reasoned that DAH could be associated with low levels of exhaled NO because of the increased availability of haemoglobin within the alveolar compartment binding NO.

A 52 year old non-smoking man with a history of allergic rhinitis and asthma was admitted with increasing dyspnoea. His asthma had been controlled by maintenance inhalation of salmeterol and fluticasone. In the previous 3 weeks the patient had experienced painful paraesthesias. On admission he was in mild respiratory distress with a peak expiratory flow rate of 415 l/min (92% of his personal best value), arterial oxygen tension (Pao2) 8.6 kPa (65 mm Hg), haemoglobin 11 g/dl, and leucocyte 23 (eosinophils 23%).

Exhaled air was collected in a sample bag according to American Thoracic Society recommendations (inspiratory air NO concentration <3 ppb, expiratory flow rate 350 l/min, and NO was sampled over 2 hours of collection using a chemiluminiscent analyser (NIOX, Aerocrine, Solna, Sweden). The initial level of exhaled NO was 4 ppb (normal reference value in our laboratory is 12 (2) ppb). Twelve hours later the haemoglobin fell to 9.1 g/dl, Pao2 was 7.2 kPa (54 mm Hg), and confluent air space opacities were apparent on the chest.

References
that, in acute pneumonia (which should be considered in the differential diagnosis), exhaled NO levels have been reported to be high, at least in the one published case series.
