Risk factors for multidrug resistant tuberculosis in Europe: a systematic review

A Faustini, A J Hall, C A Perucci

Background: The resurgence of tuberculosis (TB) in western countries has been attributed to the HIV epidemic, immigration, and drug resistance. Multidrug resistant tuberculosis (MDR-TB) is caused by the transmission of multidrug resistant Mycobacterium tuberculosis strains in new cases, or by the selection of single drug resistant strains induced by previous treatment. The aim of this report is to determine risk factors for MDR-TB in Europe.

Methods: A systematic review was conducted of published reports of risk factors associated with MDR-TB in Europe. Meta-analysis, meta-regression, and sub-grouping were used to pool risk estimates of MDR-TB and to analyse associations with age, sex, immigrant status, HIV status, occurrence year, study design, and area of Europe.

Results: Twenty nine papers were eligible for the review from 123 identified in the search. The pooled risk of MDR-TB was 10.23 times higher in previously treated than in never treated cases, with wide heterogeneity between studies. Study design and geographical area were associated with MDR-TB risk estimates in previously treated patients; the risk estimates were higher in cohort studies carried out in western Europe (RR 12.63; 95% CI 8.20 to 19.43) than in eastern Europe (RR 8.53; 95% CI 6.57 to 11.06). National estimates were possible for six countries. MDR-TB cases were more likely to be foreign born (odds ratio (OR) 2.46; 95% CI 1.86 to 3.24), younger than 65 years (OR 2.53; 95% CI 1.74 to 3.43), male (OR 1.38; 95% CI 1.16 to 1.65), and HIV positive (OR 3.52; 95% CI 2.48 to 5.01).

Conclusions: Previous treatment was the strongest determinant of MDR-TB in Europe. Detailed study of the reasons for inadequate treatment could improve control strategies. The risk of MDR-TB in foreign born people needs to be re-evaluated, taking into account any previous treatment.

Tuberculosis control, because standardised short course chemotherapy (SS-CC) is less effective in these patients and second line drugs are less effective and more toxic than first line drugs.

Either transmission of MDR strains or selection of single drug resistant strains may have contributed to the increase in the prevalence of MDR-TB in western countries. Infectivity of MDR strains is higher than was initially thought. The prevalence of infection among contacts of MDR-TB cases is similar to the prevalence among contacts of cases without MDR-TB. In closed communities such as prisons and hospitals, MDR-TB has been transmitted between immunocompetent as well as immunodeficient individuals. The selection of single drug resistant strains of Mycobacterium tuberculosis is attributable only to inadequate treatment since alternative mechanisms such as the presence of plasmids or other genetic elements has never been demonstrated for TB.

Unsuccessful treatment therefore plays a double role with respect to MDR-TB—it can be either a result of, or a risk factor for, MDR-TB. These relationships are so widely recognised that MDR-TB is classified as being due to previous treatment if the patient has been treated before, and attributed to an infection with an MDR strain of M tuberculosis if detected in newly diagnosed patients.

The World Health Organisation (WHO) has documented MDR-TB worldwide. According to the most recent data, between 1999 and 2002 the prevalence of MDR-TB was 1.7% in all cases, 1.1% in new cases, and 7% in previously treated cases. A few countries in eastern Europe and in southeast Asia are areas of concern for the dissemination of MDR-TB because drug resistant strains may be continuously created.

Abbreviation: MDR-TB, multidrug resistant tuberculosis
and circulated, as suggested by the high percentages of multidrug resistance among both new and previously treated cases.

Although many studies in Europe have focused on the prevalence of MDR-TB, only a few have dealt with risk factors and have analysed multidrug resistance separately from other drug resistances. We report here the results of a systematic review to determine the risk factors associated with MDR-TB in Europe.

**METHODS**

**Identification and selection of papers**

A systematic review of published reports dealing with risk factors for MDR-TB in Europe was carried out. Studies were identified through a computerised search of the following databases: PubMed (1993–2003), Embase (1993–2003), Toxline (1993–2003), Serfile (1998–2003), CAB abstract (1993–2003). Medline was searched through PubMed. The search terms tuberculosis, drug resistance, and multidrug resistance and any of the following—risk factors, epidemiologic determinants, predictors, treatment-outcome, treatment failure, surveillance, surveys, transmission, and spreading—were used as a combination of free text and thesaurus terms in different variations. The documents produced on the WHO website were systematically searched. The *International Journal of Tuberculosis and Lung Disease* was selected as the key journal for hand searching.

Reports of original studies from European countries were included in the review, while comments, editorials and reviews were excluded. Articles were included if they contained information allowing estimates of association between MDR-TB and risk factors. We did not report variables associated with MDR-TB as clinical predictors such as cavitary disease.

Articles were excluded if they had <10 cases or only extrapulmonary TB, if they dealt with a Mycobacterium other than tuberculosis, if they were limited to high risk groups such as HIV positive or neoplastic patients or prisoners, or if they were limited to a particular outbreak. We also excluded case reports and studies presenting results on diagnostic/laboratory methods, drug efficacy tested in vitro or through clinical trials, TB vaccination, indications for management or treatment of MDR-TB, and surgical management of resistant tuberculosis.

**Outcomes measures and definitions**

MDR-TB was defined in each paper as tuberculosis resistant to at least isoniazid and rifampicin (HR). The study population was estimated as the number of TB patients with a positive culture for *M tuberculosis* who underwent drug sensitivity analysis. European countries were selected according to the WHO regional classification, which includes Israel and Turkey.

**Statistical analysis**

Where appropriate, we used pooled risk estimates, odds ratios (ORs), and relative risks (RRs) of MDR-TB in a random effects meta-analysis (Stata Version 7). We included in pooled ORs the risk estimates obtained in all surveys, irrespective of study design. The standard error and 95% confidence intervals (CI) of risk estimates were calculated from data reported in each paper. We assessed heterogeneity between studies by using the χ² test, and variation due to heterogeneity across the studies by calculating the *I*². The factors we analysed to determine the association with MDR-TB were previous treatment, foreign born status, HIV status, age under 45, age under 65, and male sex. Whenever possible we stratified the results by country or geographical area of Europe. A regression analysis by year of TB occurrence, study design, and the proportions of patients at risk for other factors was performed.

**RESULTS**

Of 1721 articles selected from the initial PubMed search on MDR-TB risk factors, 119 were from European countries. No additional references were identified from the other

studies, explicitly excluded in one, and may or may not out between 1984 and 2000, and the number of cases studied complete data for some risk factors. Other papers included in the meta-analysis that did not report complete data on which the pooled risk estimates were the basis of the inclusion criteria. Five studies were studies reviewed in full, 29 were selected for the review on Disease and four from references in other papers. Out of 125 International Journal of Tuberculosis and Lung databases. Two additional papers were identified from a Figure 1 Odds ratio (OR) of multidrug resistant tuberculosis (MDR-TB) for previous treatment in Europe. Twelve European countries were represented in the review: the former USSR, Poland, Hungary, and Turkey from eastern Europe; Italy, Sweden, France, Switzerland, Spain, Portugal, Netherlands and Germany from western Europe. The studies were carried out between 1984 and 2000, and the number of cases studied ranged from 119 to 25 217. Chronic TB was included in three studies, explicitly excluded in one, and may or may not have been included in 20 papers. All the studies were prospective or retrospective surveys; nine were laboratory based, 10 population based, and five hospital based. The relative risk estimates were reported in six population based and two laboratory based surveys.

Figure 2 Relative risk of multidrug resistant tuberculosis (MDR-TB) in western and eastern Europe.

MDR-TB patients were more likely to have received previous treatment in 22 studies, with a pooled risk estimate 10 times higher for treated than for new patients; the association was weak and not significant in only one study (fig 1); one additional study did not analyse this factor.

The European area (p = 0.004) and the study design (p = 0.04) were associated with the risk estimates of MDR-TB for previously treated patients, while no relation was found with the proportion of patients who were male, younger than 45, HIV positive, foreign born, or the year in which the TB occurred.

We could calculate national pooled risk estimates of MDR-TB for treated patients only in six countries: the former USSR (OR 4.64), Italy (OR 24.56), Poland (OR 9.72), the UK (OR 10.55), France (OR 15.19), and Germany (OR 15.17). The pooled risk estimates for previously treated patients were lower in eastern Europe (OR 6.35; 95% CI 4.27 to 9.49) than in western Europe (OR 13.99; 95% CI 10.19 to 19.21).

The pooled risk estimates for previously treated patients was a little lower when estimated through the ORs in all studies (OR 10.23; 95% CI 7.63 to 13.70) than when estimated through RRs in the eight cohort studies (RR 12.02; 95% CI 8.11 to 17.81).
Neither location nor study design explained the heterogeneity between the studies. Heterogeneity was only explained when pooled MDR-TB risk was estimated in studies that used both a cohort design and analysed differences in risk by European area (fig 2).

MDR-TB patients were more likely to be foreign born in eight studies carried out in western Europe, although one study did not find any association between foreign status and MDR-TB (fig 3). Foreign status was not analysed at all in 15 studies, including all nine performed in eastern Europe. An additional study explicitly excluded foreign born patients.

No association was found between the risk of the MDR-TB individual being foreign born and the proportion of patients who were male, younger than 45 years, HIV positive or previously treated, the year the TB occurred, or the study design.

MDR-TB patients were more likely to be younger than 65 years (fig 4). The pooled risk of MDR-TB for people younger than 45 was lower (OR 1.52; 95% CI 1.13 to 2.03). Only five of the eight studies (22 29 32 34 36) that analysed age found an association, and the heterogeneity remained very high. MDR-TB patients were more likely to be male; heterogeneity between the studies was low although only three studies showed a clear association with male sex (fig 4). We found a stronger association with male sex (OR 1.54; 95% CI 1.31 to 1.82) in the eight studies carried out in western Europe and heterogeneity between studies very low (p = 0.207). Men were at lower risk of MDR-TB in the three studies carried out in the former USSR (OR 0.86; 95% CI 0.43 to 1.71) with a high heterogeneity between studies (χ² = 6.53; p = 0.04).

MDR-TB patients were more likely to be HIV positive (fig 5), although one study in France (35) and one in Italy (31) did not find any association with this variable, and in a further study (34) the association was limited to new cases. Sixteen studies did not analyse this factor at all and one other excluded HIV positive patients.

Finally, MDR-TB was associated with being a prisoner in the five studies which included prisoners (OR 1.75; 95% CI 0.90 to 3.40). The estimated risk of MDR-TB for prisoners was studied more frequently in countries of the former Soviet Union than in the rest of Europe.

DISCUSSION

Limitations of this study

The most important limitation of the study is the large number of papers with missing data on risk factors. Fifteen papers did not provide information on age, 16 did not report foreign status, and 12 did not list the sex of the study subjects. The large heterogeneity observed for the pooled estimate of MDR-TB in previously treated patients is likely to be due to methodological differences between the studies, such as different referent groups, misclassification of new and previously treated cases, and the inclusion of chronic cases.

There were sufficient studies on imprisonment to calculate the pooled risk factor. Other social factors such as homelessness (4) and urban residence (22) were reported in very few papers, although they were found to be associated with MDR-TB. Unemployment, (22, 23) alcohol abuse, (4, 21, 40) low education, (21, 22) and low socioeconomic status (22) were not found to be associated with MDR-TB. A more precise definition of

---

Figure 4  Odds ratio (OR) of multidrug resistant tuberculosis (MDR-TB) for age < 65 years and male sex in Europe.
M tuberculosis resistant strain of patient could have already been infected with a multidrug resistant strain of M tuberculosis independent of the first episode of TB. Even in this review, previous treatment was the strongest risk factor for MDR-TB in both patients and clinicians have each been reported as a risk factor for MDR-TB. A chronic case has been defined as a patient who is sputum positive at the end of treatment, and/or a re-infection with a resistant strain may occur when patients do not reveal previous TB. Since a history of TB may be more actively sought in those with a chronic case, this can lead to differential misclassification. In South Africa the percentage of resistant TB in new cases was estimated to be 52% by restriction fragment length polymorphism (RFLP) but only 29% on the basis of clinical history. Finally, selection bias was possible in studying TB patients for drug sensitivity as these patients were chosen by clinical criteria. Studying representative samples of all TB patients could reduce this selection bias.

Influence of immigration
Immigration has been suggested as one factor leading to the increased prevalence of MDR-TB in European countries. This review found that MDR-TB patients were more likely to be foreign born, although the strength of the association was much less than for previous treatment. The association between MDR-TB and being foreign born could be due to a higher risk of transmission of MDR strains of M tuberculosis for immigrants, but it may be confounded by previous treatment. Although we could not analyse how many foreign born patients were newly diagnosed or previously treated, a few studies in this review dealt with this problem. A French study stratifying results by country of birth found a higher risk of MDR-TB in both new and previously treated patients from sub-Saharan Africa, while patients from North Africa were at higher risk of MDR-TB only after a previous treatment. In the UK, cases treated abroad were found to be at higher risk of MDR-TB than those treated nationally, regardless of birthplace. These results suggest that previous treatment may be the most important risk factor for MDR-TB in immigrants as well as in natives, and underline the importance of controlling for this in analysing the risk of migration.

Role of age and sex
There was a clear association observed between MDR-TB and age under 65 years, but the association was weak and more heterogeneous for ages under 45. This result could reflect the year in which effective anti-tuberculosis drugs such as rifampicin were introduced. MDR-TB patients were more likely to be male in western Europe, where previous treatment was the most important determinant of MDR-TB. In eastern Europe, where the risk of transmission is greater, male sex was not a risk factor for MDR-TB. Although we did not find any influence of sex on the association between MDR-TB and previous treatment, we cannot exclude an effect of sex in modifying the association between previous treatment and MDR-TB. It could be hypothesised that women are more compliant with treatment and therefore less likely to receive inadequate treatment.

Role of HIV
Initially it seemed that HIV status was a risk factor for MDR-TB, but nosocomial outbreaks largely accounted for the association and, currently, the prevalent hypothesis is that...
HIV infection favours the transmission of multidrug resistant strains of M tuberculosis. As such, the analysis of MDR-TB incidence is useful for understanding the dynamics of transmission, especially in countries where HIV infection is high. The list of papers excluded from the meta-analysis is available in Word of Hygiene and Tropical Disease, London, UK.
