NK/T cell lymphoma of the lung: a case report and review of literature

P Laohaburanakit, K A Hardin

Primary pulmonary lymphoma is rare and is usually of B cell type. Tissue samplings taken by transbronchial biopsy and computed tomographic (CT) guided needle biopsy of the right perihilar area of an elderly woman who presented with refractory pneumonia showed T cell lymphocytosis with no evidence of active infection. The patient’s respiratory status rapidly deteriorated and she eventually died. Post mortem examination revealed primary pulmonary T cell lymphoma with natural killer (NK) cell features. We present what may be the first case of primary NK/T cell pulmonary lymphoma and review the literature on the subject.

Primary pulmonary lymphoma is rare. Most cases are of B cell origin and commonly arise from bronchial mucosa associated lymphoid tissue (MALT). Non-B cell lymphomas—that is, T cell and natural killer (NK) cell lymphomas—involving the lung parenchyma are uncommonly reported. NK/T lymphoma is aggressive and delay in establishing the diagnosis can result in a fatal outcome.

CASE REPORT

A 72 year old female non-smoker presented with shortness of breath (SOB), productive cough, and intermittent fever for 3 months. She was treated with azithromycin for community acquired pneumonia without improvement. The chest radiograph showed multiple areas of consolidation in the right lung. Initial laboratory findings revealed normal complete blood count and an unremarkable chemistry panel. A computed tomographic (CT) scan of the chest showed bilateral areas of consolidation with cavitation in the right upper lobe and diffusely distributed small nodules. No mediastinal or hilar adenopathy was noted (fig 1). Antibiotic coverage was modified to intravenous doxycycline and cefotaxime. A bronchoscopy with transbronchial biopsy (TBB) was performed. The bronchoalveolar lavage (BAL) fluid revealed 240 white blood cells (WBC)/ml with 80% lymphocytes, and the TBB showed lymphocytic inflammation. Cultures from the BAL fluid subsequently grew group B Streptococcus and parainfluenza virus, which were believed to be responsible for the lymphocytic inflammation. She improved and was discharged home only to return to the hospital 2 weeks later with worsening SOB.

A repeat CT scan of the chest showed increasing consolidation in both lungs without adenopathy and a new right sided pleural effusion. Thoracentesis was performed which also revealed a lymphocytic exudate. Cultures and cytological examination of the pleural fluid were negative. The patient underwent a repeat bronchoscopy with TBB which again indicated lymphocytic infiltration. Gram stain and special stains for atypical organisms including mycobacteria, fungi, and Pneumocystis carinii were negative. The BAL fluid cultures were negative. Flow cytometry of the BAL fluid indicated that more than 80% of the lymphocytes were T cells (CD3+) with a CD4 to CD8 ratio of 0.3.

At this point a clinical suspicion for a T cell lymphoproliferative disorder was raised. A positron emission tomographic (PET) scan was obtained in an attempt to identify the extent of the disease and an alternative site for tissue sampling. The PET scan revealed an isolated intense hypermetabolic uptake in the right middle and lower lung regions without other identifiable adenopathy. An open lung surgery was performed in which an area of lung tissue was removed for histological examination. The tissue was found to be consistent with lymphoma of NK/T cell phenotype with evidence of extensive necrosis.

biopsy was recommended to the patient which she declined. A CT guided transthoracic needle biopsy of the right perihilar area was therefore undertaken which revealed CD3+, CD20−, and CD56+ cells indicating that the cells were of T and NK cell lineages. The new finding of CD56+ lymphocytes increased the likelihood of an atypical lymphoproliferative process involving NK cells, but it cannot be considered pathognomonic for a malignant process. T cell receptor (TCR) gene rearrangement was attempted but was unsuccessful due to paucity of viable cells. The patient’s clinical condition deteriorated. She refused further evaluation and developed progressive respiratory failure and died.

Post mortem examination showed multiple masses in both lungs, hilar and mediastinal lymphadenopathy. On microscopic examination the lung tissues and enlarged lymph nodes contained uniform, round, small cells with a high nucleus to cytoplasm ratio suggestive of a malignant process. The cells were angiocentric and angioinvasive (fig 2). Special staining for leucocyte common antigen (LCA) was positive (fig 3A). The cells stained positive for CD3 and CD56 but negative for CD20 (fig 3B). As CD3 is a T cell marker, CD56 is an NK cell marker, and CD20 is a B cell marker, the immunocytochemistry showed that the malignant lymphoma cells were of T and NK lineages. TCR gene rearrangement could not be done because of the lack of viable cells at post mortem examination. Based on the neoplastic morphology and the destructive nature of the CD3+ CD56+ lymphocytes, the pathological diagnosis was primary T cell lymphoma of the lung with the possibility of NK cell overlap.

DISCUSSION
Apart from HIV related lymphoproliferative disorders, primary lymphoma of the lung is rare. While extranodal manifestations of non-Hodgkin’s lymphoma (NHL) are not uncommon, isolated involvement of the lung is found in only 3–4% of cases. Most cases reported are B cell lymphoma. The true incidence of pulmonary lymphomas other than B cell type is unknown. Tamura and co-workers reported 24 cases of primary pulmonary lymphoma, only one of which was T cell in origin. Since 1990 only 13 cases of non-B cell pulmonary lymphoma have been reported. Most of these reports are not in English. Eleven of the 13 cases are reviewed here. The clinical characteristics of these cases are summarised in table 1.

The patients were usually elderly, with a female to male ratio of approximately 2:1. Most of the cases presented with cough and dyspnoea. Only three patients were asymptomatic and were diagnosed after incidental discovery of an abnormal chest radiograph. The most common radiographic finding was bilateral diffuse nodular lesions. Mass-like consolidation, cryptogenic organising pneumonia (COP)-like lesions, hilar adenopathy, and pleural effusion were also reported. These radiographic features are also associated with bronchial MALT lymphoma and cannot be used to differentiate between non-B cell and B cell malignancy of the lung.

TBB was non-diagnostic in nine of the 11 cases. Transbronchial needle aspiration (TBNA) was obtained in one case, which was also non-diagnostic. Limited flow cytometry on BAL fluid (CD4/CD8 subpopulation analysis only) was done in two cases. An open lung biopsy (OLB) or lobectomy was eventually required in nine cases. The other two cases were diagnosed by an endobronchial biopsy of a well visualised mass, and by a cervical lymph node excisional biopsy. Immunocytochemistry of the surgical biopsy specimens showed T cell markers in all cases. None of the cases reported simultaneous NK cell markers on the tumour cells. Genotypic assessment—that is, TCR gene rearrangement—was not reported in any of the cases.

Treatment consisted of CHOP (cyclophosphamide, adriamycin, vincristine and prednisone) based chemotherapy in eight patients with varying success. Four patients subsequently died and four were still living by the time the reports were published. Boon et al and Hanawa et al reported dramatic clinical and radiographic response to systemic corticosteroid alone without chemotherapy. In one case corticosteroid was used as a temporary measure until the patient could tolerate OLB.

Surgical resection was performed on three patients. In two cases the tumours were focal and the lobectomy led to cure. The pathology and immunocytochemistry of the third patient showed mixed T cell lymphoma and squamous cell carcinoma of the lung. Adjuvant chemotherapy for lym-

Phenotypic and genotypic studies. Histopathological examination usually reveals cytological dysplasia, homogeneous populations of cells, and marked architectural effacement. Although non-specific, morphological features are useful in directing the subsequent work-up for diagnosis. Immunophenotyping using immunohistochemistry or the much more sensitive flow cytometry is valuable in defining the lineage of origin. Finally, the clonality is demonstrated by TCR gene rearrangement.

In conclusion, lymphoma of the lung is extremely rare and is typically of B cell lineage. Non-B cell lymphoma of the lung is an unusual diagnosis and warrants high clinical suspicion. Its presence portends a poor prognosis. To our knowledge, we report the first case of non-HIV related NK/T cell lymphoma with primary lung involvement. Diagnosis is difficult and, because of its aggressive nature, a delay in diagnosis and treatment usually leads to a fatal outcome. It should be included in the differential diagnosis of progressive or unresolved pneumonia, especially when T cell lymphocytosis is persistent in the absence of a well defined infectious aetiology. A definitive diagnosis always requires adequate viable tissues for morphological, immunocytochemical, and molecular studies.
molecular analyses. TBB, transthoracic needle biopsy, and TBNA are generally insufficient and early open lung biopsy or video assisted thoracoscopic lung biopsy should be considered. In view of its extreme rarity, there is no recommended treatment at present. CHOP based chemotherapy and surgical resection have been reported in the literature. The response to chemotherapy is variable. Surgical resection may offer a cure in a patient whose tumour is localised. Systemic corticosteroids may be tried as a temporary measure to stabilise the patient sufficiently to undergo surgical biopsy.

LUNG ALERT
Implication of ANCA status in Churg-Strauss syndrome

Patients with ANCA had a higher frequency of renal involvement (35% v 4%) and peripheral neuropathy (84% v 65%) than those without ANCA. In addition, vasculitis was more often observed in the biopsy specimens of the ANCA positive patients (79% v 39%). On the other hand, patients without ANCA were more likely to have fever (55% v 30%) and cardiac disease (49% v 12%). One limitation of the study was that patients who were initially ANCA negative were not retested.

The authors hypothesise the presence of two phenotypes of Churg-Strauss syndrome on the basis of the ANCA status. They conclude that the latter reflects the underlying pathophysiology of the disease, with the presence of ANCA favouring the likelihood of a vasculitis affecting certain organs. Further work is required to determine what effect these findings might have on treatment.
