lumen. Pathologically, two forms of BO exist: complete obliteration of the airway leading to narrowing and/or complete obstruction of the terminal bronchioles that lead to narrowing and/or complete obliteration of the lower respiratory tract. It is characterised by inflammation and fibrosis of the terminal and respiratory bronchioles that lead to narrowing and/or complete obstruction of the airway lumen. Pathologically, two forms of BO are recognised, and these may be part of a continuum. Proliferative bronchiolitis is characterised by intraluminal exudates, whereas constrictive bronchiolitis is characterised by alterations in the walls of the bronchioles ranging from inflammation to fibrosis and, ultimately, to complete obliteration of the lumen.

References
that the prevalence of BO appears to be increased in Native Americans in Canada,
and Native Koreans. A recent study found that HLA-DQB1*0302, an antigen highly represented in Amerindians, was increased in children with BO in Argentina.

In this issue of Thorax Colom et al present the first systematic study examining the risk factors associated with the development of BO in children. Given the relatively high incidence of BO in Argentina, the authors have accumulated extensive experience with this disorder and have a unique opportunity to study this relatively rare disease. Although the association between adenovirus infection and BO in children has been well recognised, this study convincingly shows that adenovirus is by far the most common cause of post-infectious BO. The additional finding that mechanical ventilation is an independent risk factor for the development of BO is not surprising, but this association has never been previously examined. The authors are careful to point out that their data do not allow them to determine whether mechanical ventilation contributes to the development of BO or simply reflects the severity of the acute insult. This paper therefore presents important new information that contributes to our understanding of risk factors predisposing to BO in children.

Formally evaluating this rare disease is problematic for many reasons. Most importantly, perhaps, is that no single classification scheme has been widely accepted. Pathological, clinical, and radiological classification schemes have been proposed, mainly for BO in adults. Although the histopathological subtypes can be classified by the pathologists, the clinical and radiological correlates are not always obvious. Furthermore, even though histopathology is considered the gold standard for diagnosis, the non-homogenous distribution of pathology in the affected lung can lead to sampling error when attempting to diagnose BO by biopsy. Thus, definitively diagnosing this disorder remains problematic, even with lung biopsy. In this study the authors chose to define BO using clinical criteria that they had previously employed to describe the clinical signs and symptoms associated with chronic pulmonary disease following severe adenoviral illness in children. Using infant lung function techniques, they found that these young children had severe fixed bronchial obstruction, decreased pulmonary distensibility, and increased airway resistance. They concluded that their findings might represent the functional expression of the histopathological damage of BO. Since lung biopsies are often non-diagnostic in BO and carry risks, the clinical definition developed by the authors, although imperfect, seems appropriate to identify the cohort of children who developed severe post-infectious obstructive lung disease in the current study.

Although not a primary focus of this study, one additional interesting and important observation was the excellent long term outcome of the patients with BO. This finding supports the impression of many of us that post-infectious BO in children carries a better prognosis than other forms of BO, particularly those that occur in adults. Given the limitations of its retrospective design, this study represents a good first step in the systematic evaluation of children with BO. Whether these findings can be extrapolated to BO in other parts of the world remains to be seen.

Further research is needed to ascertain the mechanisms by which adenovirus—more than other respiratory pathogens—contributes to the development of BO. Additional investigations should be done to define more clearly the specific value of clinical presentation, pulmonary function testing, high resolution computed tomography, and lung biopsy in the diagnosis of BO in children. Surrogate markers of disease activity need to be developed. For example, preliminary studies suggest that KL-6, a protein expressed by activated pulmonary epithelial cells, is increased in the serum of lung transplant patients who develop BO. Whether KL-6 would be a useful marker in post-infectious BO should be evaluated. Finally, systematic studies are needed to determine if treatments such as infliximab and azathioprine, suggested for other forms of BO, are effective in improving the outcome of patients with post-infectious BO.
