Traffic exposure and lung function in adults: the Atherosclerosis Risk in Communities study

Haidong Kan, Gerardo Heiss, Kathryn M Rose, Eric Whitzel, Fred Lurmann, Stephanie J London

Background: Traffic exposure is a major contributor to ambient air pollution for people living close to busy roads. The relationship between traffic exposure and lung function remains inconclusive in adults.

Methods: A cross-sectional study was conducted to investigate the association between traffic exposure and lung function in the Atherosclerosis Risk in Communities (ARIC) study, a community based cohort of 15,792 middle aged men and women. Traffic density and distance to major roads were used as measures of traffic exposure.

Results: After controlling for potential confounders including demographic factors, personal and neighbourhood level socioeconomic characteristics, cigarette smoking and background air pollution, higher traffic density was significantly associated with lower forced expiratory volume in 1 s (FEV1) and forced vital capacity (FVC) in women. Relative to the lowest quartile of traffic density, the adjusted differences across increasing quartiles were 5.1, -15.4 and -21.5 ml for FEV1 (p value of linear trend across the quartiles = 0.041) and 1.2, -23.4 and -34.8 ml for FVC (p trend = 0.010). Using distance from major roads as a simpler index of traffic related air pollution exposure, the FEV1 was -15.7 ml (95% CI -34.4 to 2.9) lower and the FVC was -24.2 ml (95% CI -46.2 to -2.3) lower for women living within 150 m compared with subjects living further away. There was no significant effect of traffic density or distance to major roads on lung function in men. The FEV1/FVC ratio was not significantly associated with traffic exposure in either men or women.

Conclusions: This is the largest published study of traffic exposure and pulmonary function in adults to date. These results add to growing evidence that chronic exposure to traffic related air pollution may adversely affect respiratory health.

Methods

Study population

Participants were from the ARIC study which is designed to investigate the natural history and aetiology of atherosclerosis and its sequelae. The design, objectives and quality control activities of the ARIC study have been reported in detail elsewhere.18 19 Participants were sampled from four US communities: Forsyth County, North Carolina; Jackson, Mississippi; northwest suburbs of Minneapolis, Minnesota; and Washington County, Maryland. The lung function variables collected during visit 1 (1987–9) were used with the traffic and background air pollution data in a cross-sectional analysis. Participants of an ethnicity other than African American or white were excluded from the current analysis (n = 48). Also, African-Americans from Minnesota and Maryland field centres were excluded (n = 55) because of their small number.

We also repeated this analysis using visit 2 (1990–2) and conducted a longitudinal analysis on the change in lung function between visit 1 and visit 2.

Pulmonary function measurements

The main measurements of lung function were forced expiratory volume in 1 s (FEV1), volume of gas (in litres) exhaled in the first second of expiration; forced vital capacity (FVC), total volume of gas exhaled; and the ratio of FEV1/FVC.

Abbreviations: ARIC, Atherosclerosis Risk in Communities; BMI, body mass index; ETS, environmental tobacco smoke; FEV1, forced expiratory volume in 1 s; FVC, forced vital capacity; GIS, geographical information system; PM10, particulate matter <10 μm
Quality control was carefully conducted throughout the study, as described previously. 20

Geocoding
Participant addresses were geocoded using a commercial service (Mapping Analytics LLC, Rochester, New York, USA) which assigned a latitude and longitude coordinate to each address. This geocoding was performed with the Centrus Enhanced Database which was primarily based on the Topologically Integrated Geographic Encoding and Referencing system (TIGER) data. Visit 1 addresses for 13 972 participants (88.4%) were successfully geocoded.

Traffic exposure
We quantified small scale spatial variations in traffic exposure by two measurements: geographical information system (GIS) mapped traffic density assignments at residences, and the distance of residences to nearest roadways of four types—interstate highways (road class 1), state highways (road class 2), major arterial roads (road class 3) and local roads (road class 4).

Traffic density
Traffic density data were generated using a decay function that approximates the potential influence of activity weighted mobile source emissions at various distances from a roadway. This method accounts for the combined relative influence of several roadways (and road types) with various traffic activity levels at different distances from each residence location. The metric generally behaves like an inverse distance weighted traffic volume, except that it specifically considers intersections and multiple roadways more accurately. These density values therefore give a relative indication of which residence locations are likely to be most exposed to traffic activity and, as such, are dimensionless indicators of proximity to traffic volume.

Because the available traffic density data were from 2000, we back extrapolated to the study period (1987–92) based on change in population density using county level census population data. Changes in traffic volumes over time are correlated with changes in population density. 21

Distance to major roads
To estimate qualitatively the distribution of the distance from residence locations to roadways, straight line distances were calculated. The distance to roadway data include the distance (in metres) from each unique residence location to the nearest roadway for the four road classes. Given inherent imprecision in geocoding and assessment of distances to roads, minimums were set to 30 m for class 1 roads, 20 m for class 2 roads, 10 m for class 3 roads and 10 m for class 4 roads.

Consistent with previous literature, 22–24 we dichotomised distance to major roads (interstate and state highways, major arterials) at 150 m. In addition, we conducted a sensitivity analysis and categorised distance to major roads as <100 m and ≥100 m. 12

Background air pollution level
Data on the background ambient concentrations of particulate matter <10 μm (PM10), nitrogen dioxide and ozone during the research period were acquired from the Environmental Protection Agency air quality data retrieval system. We abstracted 24 h average concentrations of PM10 and nitrogen dioxide and 8 h (10.00 to 18.00 h) average concentrations for ozone. The average concentrations during our research period (1987–92) were spatially interpolated from air quality monitoring stations to the cohort residence locations using inverse distance weighting.

Other covariates
Anthropometric measures were determined by trained certified technicians following a standardised protocol. Interviewers collected information on age, ethnicity, sex, smoking, environmental tobacco smoke (ETS) exposure, occupation, education, medical history and other factors.

Neighbourhood level socioeconomic factors, in addition to individual level factors, may have an impact on health status. 25 We therefore included 1990 census tract level data on median household income, median vehicle number per housing unit, employment rate and poverty rate. 26

Statistical analysis
Distributions of traffic density are highly skewed (see fig 1, drawn in SPSS Version 11.0, Chicago, Illinois, USA) so we analysed traffic density in quartiles. SAS Version 9.1.2 (Cary, North Carolina, USA) software was used for statistical analyses. Based on previous literature, potential confounding factors including research centre, ethnicity, age, smoking status (never, former and current) and pack years, ETS, body mass index (BMI), occupation, educational level, height, square of height, census tract socioeconomic factors (median household income, median vehicle number per housing unit, employment rate, and poverty rate) and background air pollution level were included in the analysis. The square of height was used because it explained more variation in lung function measurements than height. 27 BMI and pack years were treated as quintiles given their non-linear relationships with FEV1 and FVC. When jointly modelling individual and census tract level measures, hierarchical regression (SAS PROC MIXED) was employed as it provides variance estimates which have been adjusted to take into account the dependence of measures from the same areas. Factors potentially modifying the exposure to traffic (sex, smoking and ethnicity) were evaluated for possible inclusion as interaction terms with traffic exposure.

RESULTS
Participant description
Table 1 shows selected characteristics of the participants at baseline, overall and by sex. The mean age of the participants was 54.2 years. Compared with men, women were slightly younger, less likely to smoke, more likely to be African Americans and had a slightly higher BMI.

Subjects in the highest quartile of traffic density and those living closest to major roads were slightly older, had slightly higher BMI values and were more likely to be current smokers (tables A2 and A3 in the appendix available online at http://thorax.bmj.com/supplemental). Those living closer to main roads (<150 m) had resided in lower neighbourhood socioeconomic areas. Patterns were similar in men and women.

The estimated traffic density and background air pollutant (PM10, nitrogen dioxide and ozone) concentrations at the visit 1 home address varied greatly among participants (fig 1). Consistent with previous reports, 28 we did not find a strong correlation between traffic density and background air pollution level; the Pearson correlation coefficients of traffic density with PM10, nitrogen dioxide and ozone were −0.12, −0.04 and −0.10, respectively.

Table 2 shows the distributions of the estimated distances from the home address at visit 1 to four types of roads; 5444 (39.0%) participants lived within 150 m of major roads (road classes 1–3) and only 264 (1.9%) participants lived within 150 m of an interstate highway.

Traffic exposure and lung function

Because we observed a significant interaction between sex and traffic density for FVC (p = 0.041), the relationships between measures of traffic exposure and lung function are presented using sex-specific multivariate regression.

Both before and after adjustment for confounders, an inverse relation was found between lung function and traffic density among women (table 3). Relative to the lowest quartile of traffic density, the adjusted differences across increasing quartiles were 5.1, −15.4 and −21.5 ml for FEV1, and 1.2, −23.4 and −34.8 ml for FVC. This linear trend was significant for both FEV1 (p = 0.041) and FVC (p = 0.010). We did not find a clear association between traffic density and FEV1 or FVC in men (table 4).

A similar pattern, although of lower statistical significance, was seen for living near major roads. Among women living within 150 m of a major road, the FEV1 was −15.7 ml (95% CI −34.4 to 2.9) lower and the FVC was −24.2 ml (95% CI −46.2 to −2.3) lower in multivariate analyses compared with women living further away (table 5). In a sensitivity analysis using different cut off points (≥100 m and <100 m), similar but weaker patterns were found in women (table 5). We did not observe significant effects of distance in men.

The ratio of FEV1/FVC was not significantly associated with traffic density or distance to major roads in either sex (tables 3–5).

We did not observe a significant effect modification of the association between traffic density and lung function by smoking (p = 0.989 for FEV1 and 0.867 for FVC) or ethnicity (p = 0.371 for FEV1 and 0.147 for FVC).

When the analyses were repeated using traffic exposure and lung function data obtained at visit 2, the associations were generally similar to those described for visit 1 (see tables A7 and A8 in the online appendix available at http://thorax.bmj.com/supplemental).

Given the small effect of traffic in our study and earlier publications36–42 and because we had only two pulmonary function measurements spaced 3 years apart, we did not anticipate being able to detect an effect of traffic on change in pulmonary function. Nonetheless, we performed supplementary longitudinal analyses. No significant associations were found (see tables A9 and A10 in the online appendix available at http://thorax.bmj.com/supplemental).

DISCUSSION

This study provides evidence that lung function, as measured by FEV1 and FVC, is reduced in adults exposed to higher levels of traffic, especially among women. To our knowledge, this is the first population-based study in the USA and the largest one to date in the world to investigate the relation between measured traffic exposure and lung function in adults. The magnitude of the observed association between traffic exposure and lung function was similar to reported effects of outdoor air pollution29 and smaller than effects of personal smoking30 or ETS exposure.11

As in some other studies,12–36 we did not find a significant association between the FEV1/FVC ratio and measures of traffic exposure. This suggests that the traffic related reduction in FEV1 and FVC was probably due to loss of lung volume (restriction) rather than airflow obstruction. Of course, a reduced FVC in the presence of a normal FEV1/FVC can be used to suggest—but not to diagnose—the presence of a restrictive abnormality.37

There are relatively few published studies of traffic related air pollution and lung function in either children or adults. In the Netherlands, investigators found that exposure to traffic related air pollution, especially diesel exhaust particles, was associated with reduced lung function in children living near major motorways.38 A German study suggested that exposure to a pollution profile of heavy traffic and domestic heating was related to markedly lower FVC and FEV1 in children.39 Several recent studies on traffic air pollution provide some support for our finding.40–42 An 8-year longitudinal study of 5682 women in Tokyo showed a larger decrease in FEV1 for participants with more exposure.”

higher traffic density. In a cross-sectional Thai study reported that the FEV₁ and partial expiratory flow volume in 78 police in Bangkok (with high traffic exposure) was much lower than in 68 police in a rural area. In a cross-sectional study of 4757 German women, living near a major road had a detrimental effect on lung function, and the patterns are not conclusive. In children, several studies found stronger effects of air pollution on respiratory symptoms and lung function in girls than in boys. In adults, studies in the USA and Switzerland found similar effects in both sexes, but automobile exhaust was associated with respiratory symptoms.

We found clearer associations in women than in men. Our measures of traffic exposure, traffic density and distance to major roads were inversely associated with lung function only in women. Few studies have reported stratified analyses of air pollution health effects by sex, and the patterns are not conclusive. In children, several studies found stronger effects of air pollution on respiratory symptoms and lung function in girls than in boys. Conversely, in the Children’s Health Study (CHS), the effect of traffic air pollution on lung development was stronger in boys than in girls. Gehring et al also found a stronger effect of traffic air pollution on respiratory symptoms in boys than in girls. In adults, studies in the USA and Switzerland found similar effects in both sexes, whereas Abbey et al observed an association between lower lung function and long term exposure to particles only in men.

Our finding of a stronger association of reduced lung function with greater traffic exposure in women is consistent with some studies showing that women experience a greater smoking related decline in lung function than men, but not others. Compared with men, women have slightly greater airflow reactivity so dose-response relations may be detected more easily. In addition, the validity of the exposure may vary by sex and could partly explain the observed sex difference in our data. At visit 1, 35% of women but only 17% of men reported being home makers, unemployed or retired. Thus, women may, on average, have spent more time at home than men. While we cannot confirm this with our data, this has been reported in other studies. Our exposure assessment based on home address might therefore better reflect the true exposure level for women than for men.

We did not observe an effect of background air pollution on lung function. This is not surprising given that the ARIC study was not designed to examine air pollution and was limited to four communities. Furthermore, as these communities were not well supplied with air pollution monitors during the study period, little variation in air pollution within communities was captured by the available measurements.

Motor vehicle emissions, the principal source of ambient air pollution in most urban areas, are likely to vary substantially even within a given community. Research has documented differences in traffic related pollutants on a neighbourhood scale. The traditional exposure assessment relying on a small number of monitors might not therefore estimate individual exposure in the way

www.thoraxjnld.com
exposure levels adequately. In early epidemiological studies of the health effects of traffic exposure, the self-reported proximity of the home address to major roads and self-reported road type and traffic density were used. In contrast, we used objective measures of traffic related air pollution at residential addresses such as GIS based assessment of traffic density and distance to major roads.

The limitations of our analysis should be noted. Because the geocodes for participants’ addresses at visits 1 and 2 (1987–92) were obtained from the TIGER file by Mapping Analytics, error could result from the use of older road network data. To assess this we randomly selected 100 participants from each of the ARIC communities and re-geocoded their residential addresses using the GDT software which incorporates a more recent road network database. Using these new geocodes, we re-calculated the traffic densities and distances to major roads and compared them with the original results. The two geocoding methods resulted in similar estimates for the distance to nearest major roads (data not shown). For traffic density, the two methods yielded quite concordant values for the Forsyth, Jackson and Minneapolis communities, but concordance was lower for Washington County. This might reflect a renaming of streets that occurred there. We therefore repeated our analyses excluding Washington County from our analysis. With the less precise exposure assessment in Washington County excluded, the associations of traffic exposure with FEV1 and FVC became modestly stronger despite the reduced sample size (tables A11 and A12 in the online appendix available at http://thorax.bmj.com/supplemental). These additional analyses suggest that the association we observed is relatively robust to geocoding error.

We used a relatively simple proxy for traffic related air pollution (traffic density and distance to major roads) and did not attempt to model the concentrations of traffic related air pollution or to validate our exposure assessment with measurements. Although recent data suggest stronger associations with stop-and-go traffic than moving traffic and with truck traffic compared with car traffic, like most studies we could not classify traffic by type. We did not consider the acute effect of traffic exposure on lung function; however, given evidence that the association between the daily ambient level of air pollution and daily means of lung function is smaller in magnitude than the association between the long-term level of ambient air pollution and average lung function, we suspect that any bias introduced by not controlling for the acute effect of traffic exposure would be minimal.

We lacked assessment of traffic related air pollution on approximately 11.6% of subjects (10.0% of women and 13.5% of men) whose addresses could not be geocoded. This raises concern about potential selection bias. However, when we compared pulmonary function measurements and demographic characteristics in ARIC participants with and without geocoded addresses (table A1 in the online appendix available at http://thorax.bmj.com/supplemental), we did not find significant differences. It is therefore unlikely that the data missing for 10.0% of women would have created the observed associations. Our exposure assessment was limited to residential address and we did not have information on duration of residence or on home exposures to other sources of pollutants such as cooking or heating. However, it is reassuring that an earlier study of ARIC participants reported very high concordance between county and state of residence in past decades to that at visit 1, and in a study based on a sub-cohort of ARIC participants, more than 60% of subjects had addresses at ages between 30 and 50 years that were assigned latitudes and longitudes almost identical to those associated with their visit 1 address.

As in any epidemiological study, residual confounding is possible. However, we adjusted for known and potential confounders including demographic characteristics, personal and neighbourhood level socioeconomic characteristics, cigarette smoking and background air pollution. The cross-sectional nature of our data, as well as initial non-response, is also a limitation of our data.

A major strength of our analysis is that it was based on a large community based cohort from four US communities. We also had an objective and quantitative respiratory outcome—namely, lung function. In addition, both exposure and outcome data were collected at the individual level together with extensive data on potential confounders. There is evidence that, in addition to individual level factors, the residential area or neighbourhood may have an additional effect on health. Therefore, in the current analysis we also adjusted for a community level measure of socioeconomic status to help account for confounding.

In summary, in the ARIC study, higher exposure to traffic—as measured by traffic density and distance to roadways—was related to modestly reduced lung function in women. To our knowledge, this is the largest study of traffic exposure and pulmonary function to date. Our results add to growing evidence that chronic exposure to traffic related air pollution may adversely affect respiratory health.

ACKNOWLEDGEMENTS

The authors thank the staff and participants of the ARIC study for their important contributions. They also thank Joy Wood, Grace Chiu, Qing Peng, Tami Funk and Bryan Penfold for their assistance.

Further data are available in the appendix available online at http://thorax.bmj.com/supplemental.
