PCD are slowly being unravelled, owing to the multiple phenotypes of the disease and more than 200 different proteins used to construct the ciliary axoneme, it is likely to be some time before such tests are widely used in the diagnostic examination of patients with PCD.

The diagnostic service is able to accept appropriate referrals from hospital consultants. However, the service does not extend to providing care for patients diagnosed with PCD. As experience of care for patients with PCD is limited, we would suggest a model similar to that for CF where patients should have access to a specialist paediatric respiratory consultant or thoracic physician with an interest in CF or non-CF bronchiectasis and be followed up regularly for life. The diagnostic service will allow a national database of patients with PCD to be established, facilitating clinical trials to help provide an evidence base for management. An active PCD patient and parent support group has been established which we encourage newly diagnosed patients to contact (www.pcdsupport.org.uk).

Biomarkers in COPD

Biomarkers in COPD: time for a deep breath

R A Stockley

Biomarkers need to fulfil several distinct requirements before they can be considered a valid indicator of chronic diseases such as COPD

Chronic obstructive pulmonary disease (COPD) has become recognised as a priority area for management of healthcare resources and development of new therapeutic strategies. This is based largely on economic burden and the excessive morbidity and mortality associated with the condition. The result has been a profusion of publications in recent years, many of which start with the observations that “COPD is currently the fifth and by the year 2020 will become the third or fourth leading cause of morbidity and mortality worldwide”.

More recently, the COPD literature has entered a second phase. This has arisen from the appreciation that COPD is more than a respiratory inflammatory condition and is associated with manifestations outside the lung. This has led to the concept that COPD is a systemic disease and has resulted in a rapid increase in papers exploring this aspect. Initial studies were primarily based on the association of reduced body mass index with severe COPD and common inflammatory pathways have been implicated. In particular, the central role of tumour necrosis factor (TNF)α has been proposed, and muscle biopsies in patients with COPD have shown apoptotic changes within skeletal muscle thought to be the result of the systemic inflammation.

In addition to the association of skeletal muscle dysfunction, it is also being appreciated that other co-morbidities such as cardiovascular disease, type II diabetes and osteoporosis are more commonly associated with patients with COPD than the general population. Indeed, the inflammatory basis for these other conditions is also gradually becoming appreciated, and there are many common pathogenic processes between them and COPD.

Research in COPD is now entering its third phase. Many pharmaceutical companies are becoming involved in drug discovery programmes based on the development of new treatments to modulate the inflammatory processes in COPD. However, as with all chronic diseases, the progression of COPD is slow but continuous. Thus, not only does the complexity of the inflammatory pathway present a challenge to research workers and pharmaceutical companies, but also the conventional pathway of progressing from drug discovery through phase I and phase II to phase III controlled clinical trials is impaired by the lack of early “read outs” in phase II.

The traditional surrogate for progression in COPD is a physiological measurement (forced expiratory volume in 1 s (FEV₁)) which can vary day-to-day more than the overall progression over several years. Thus, although many drugs have been developed and marketed based on FEV₁ and evidence of symptomatic relief, the progression of the disease has remained unaltered. As interventions related to progression require many years of physiological follow-up, pharmaceutical companies have been hampered by the lack of specific or surrogate markers (closely linked to the pathogenic process in COPD) that are sensitive to facilitate short-term phase II proof of concept studies. Since these are the key to subsequent investment in large and lengthy phase III studies, there is an urgent need to identify such biomarkers. Understanding the inflammatory process involved in the pathophysiology of chronic diseases such as COPD provides the potential to identify more robust surrogate markers of the disease process that are sensitive to short-term interventions.
Nevertheless, identifying relevant biomarkers—although the key—is only the first step and thereafter validation becomes critical. Despite this, there is now a profusion of papers looking at both the local and systemic inflammatory processes in COPD, often compared with healthy smokers, patients with COPD who are undergoing exacerbations of their disease (when inflammation increases) and comparing these markers with lung function. This has, however, raised a significant problem of how to interpret such studies.

Although many potential mechanisms have been implicated in the pathophysiology of COPD, the role of proteolytic enzymes has been dominant for over 40 years. This is related to the initial observation that patients with α₁-antitrypsin deficiency (a genetic deficiency of a key serine proteinase inhibitor) were particularly susceptible to developing emphysema. Since animal models showed that the instillation of enzymes normally controlled by α₁-antitrypsin into the lungs produced emphysema, the proteinase/antiproteinase theory of COPD has evolved. This is based on the concept that proteolytic enzymes can produce many of the clinical and pathological features of patients with COPD, and that inflammatory processes lead to the release of proteolytic enzymes within the lungs. Excess release of such proteinases, or a net reduction in the inhibitors required to control them, would lead to the persistent enzyme activity and tissue damage producing the features of COPD.

This simple concept initially related to serine proteinases and the serine proteinase inhibitors α₁-antitrypsin (produced by the liver) and secretory leucoproteinase inhibitor which is produced locally. However, it has since become clear that such a straight pathway is an oversimplification and a cascade of proteinases and proteinase inhibitors interact, even if the common final pathway is tissue damage caused by neutrophil serine proteinases (fig 1). Furthermore, the use of a series of transgenic or knock-out mice has indicated that this protease cascade is linked to other critical steps in the inflammatory pathway, including TNFα and its receptors. For this reason, TNFα itself may be an important biomarker for the link between inflammation and tissue damage, and TNFα has been implicated in the systemic effects of muscle wasting. However, taking this forward provides a significant challenge of relating a local problem within the lung to a systemic inflammatory process where sampling and co-morbidities create confounding issues. In addition, the validation of biomarkers suffers from the problems of cross-sectional versus longitudinal observations, and whether the markers being identified are predictive or reflective of the disease process being studied.

An ideal biomarker is a direct indicator of the process being studied. It has to be reproducible, easily measured and would have to be sensitive to effective interventions. For instance, TNFα has been implicated in the pathogenic processes of insulin resistance in humans. This concept is supported by studies of the obese insulin resistant mouse which showed that antagonism of TNFα leads to the development of insulin sensitivity. TNFα has also been implicated in osteoporosis, and specific interventions not only lead to an increase in bone thickness but also a reduction in TNFα production. In vascular disease, several recent studies have indicated that measuring serum C-reactive protein (CRP) predicts future vascular events, and CRP has also been implicated in the pathophysiological pathway leading to atheroma. Studies have also shown that statins not only reduce cholesterol but can reduce CRP, which could account for the subsequent reduction in cardiovascular events.

With this as a background, similar approaches are now being undertaken in COPD. For instance, CRP in the plasma is increased in COPD and can predict the likelihood of future outcomes, although it is difficult to implicate this acute phase protein in the pathophysiology of COPD. Indeed, it is more likely to be secondary as it is known that interleukin (IL)-6 stimulates CRP production in hepatocytes as it is known that interleukin (IL)-6.

Figure 1  Proteinase and proteinase inhibitor cascade showing the inter-relationship between cysteine, serine and metalloproteinases. Individual proteinases can activate proteinases in another class and, at the same time, inactivate the relevant inhibitors. The net result is a cascade where the presence of several classes of proteinase can facilitate the end result of damage by an individual enzyme or in an additive way. MMP, matrix metalloproteinase; α₁-AT, α₁-antitrypsin; TIMP, tissue inhibitor of metalloproteinases; SLPI, secretory leucoproteinase inhibitor.

However, some studies do show a relationship between increasing concentrations of mediators and decreasing lung function. Nevertheless, even with such relationships, the concern regarding whether this is cause or effect remains a key issue.

Lung function in COPD shows progression with time but does not follow a straight line. As the FEV₁ is a measure of airflow within the airways, there has to be a major change in obstruction of the small airways before the FEV₁ is affected. Thus, lung damage in COPD can progress for a long time before the FEV₁ declines, and many subjects with a normal FEV₁ are not at risk.

Once the FEV₁ starts to decline, it does so rapidly in subjects at risk. However, in the presence of severe disease, rapid decliners are less likely to survive and long-term follow-up only relates to patients whose FEV₁ decline has stabilised (the survivor effect). This produces the characteristic sigmoid curve for decline in FEV₁, and this observation has raised questions about the nature of the relationship of biomarkers to lung function. The argument has been that any biomarker that shows an increased value related to FEV₁ in a cross-sectional study is more likely to be reflective than predictive. However, even in cross-sectional studies, that is not necessarily the case. Figure 2 shows how an individual biomarker of susceptibility to disease progression relates to the severity of disease in cross-sectional studies. If individuals with chronic disease have varying degrees of low grade inflammation, the biomarker may be largely within the normal range as for cardiovascular disease and CRP. Before the disease becomes physiologically detectable, measurements would represent three different populations: those not particularly at risk, those with a moderate risk and those who are specifically at risk. As varying degrees of severity of the disease are studied, those most at risk would become relatively more over-represented in the cohort. This would result in an increase in the average concentration of the biomarker being studied towards the level of those most at risk. Thus, such data may provide initial confidence that the biomarker being studied is related to the disease process.

However, further studies are then clearly necessary to provide final reassurance. This requires longitudinal studies relating the initial biomarker to subsequent progression, as has been shown with airway mediators in COPD, and is likely to be easier if the mediator plays a recognised role in the pathophysiology rather than a general role in inflammation. With this concept in mind, it is difficult to understand or reconcile two recent studies showing that baseline CRP relates to the decline in FEV₁ in mild to moderate COPD but not in population screening. Perhaps, unlike cardiovascular disease, biomarkers in lung disease are only informative once the disease is established. Clearly these recent studies emphasise the complexity of biomarker studies during this period of their infancy.

The study of biomarkers is of major importance in developing new therapeutic strategies for chronic slowly progressive diseases. However, to be valid, the biomarker needs to fulfil several distinct requirements.

- It must be central to the pathophysiological process implicated in the disease.
- It must therefore reflect or be a very clear surrogate of that disease process.
- It must be stable and only vary with events known to relate to disease progression.
- Those at risk with a higher value at baseline must become more prevalent as disease severity or its prevalence increases.
- The biomarker must predict progression.
- The biomarker must also be sensitive to intervention factors that are known to be effective; this may prove the biggest hurdle.

However, once all these boxes are ticked, the biomarker can be used as an early read out of therapeutic efficacy with a reasonable degree of confidence.

In summary, before we get carried away with continued measurements of a multitude of factors that have some link to inflammation in COPD, it is important that we take a deep breath and rethink our concepts of the inflammatory process and design and deliver our studies appropriately and with care.

**BMJ Clinical Evidence—Call for contributors**

**BMJ Clinical Evidence** is a continuously updated evidence-based journal available worldwide on the internet which publishes commissioned systematic reviews. **BMJ Clinical Evidence** needs to recruit new contributors. Contributors are healthcare professionals or epidemiologists with experience in evidence-based medicine, with the ability to write in a concise and structured way and relevant clinical expertise.

**Areas for which we are currently seeking contributors:**
- Secondary prevention of ischaemic cardiac events
- Acute myocardial infarction
- MRSA (treatment)
- Bacterial conjunctivitis

**Being a contributor involves:**
- Selecting from a validated, screened search (performed by in-house Information Specialists) valid studies for inclusion.
- Documenting your decisions about which studies to include on an inclusion and exclusion form, which we will publish.
- Writing the text to a highly structured template (about 1500–3000 words), using evidence from the final studies chosen, within 8–10 weeks of receiving the literature search.
- Working with **BMJ Clinical Evidence** editors to ensure that the final text meets quality and style standards.
- Updating the text every 12 months using any new, sound evidence that becomes available. The **BMJ Clinical Evidence** in-house team will conduct the searches for contributors; your task is to filter out high quality studies and incorporate them into the existing text.
- To expand the review to include a new question about once every 12 months. In return, contributors will see their work published in a highly-rewarded peer-reviewed international medical journal. They also receive a small honorarium for their efforts.

If you would like to become a contributor for **BMJ Clinical Evidence** or require more information about what this involves please send your contact details and a copy of your CV, clearly stating the clinical area you are interested in, to CECommissioning@bmjgroup.com.

**Call for peer reviewers**

**BMJ Clinical Evidence** also needs to recruit new peer reviewers specifically with an interest in the clinical areas stated above, and also others related to general practice. Peer reviewers are healthcare professionals or epidemiologists with experience in evidence-based medicine. As a peer reviewer you would be asked for your views on the clinical relevance, validity and accessibility of specific reviews within the journal, and their usefulness to the intended audience (international generalists and healthcare professionals, possibly with limited statistical knowledge). Reviews are usually 1500-3000 words in length and we would ask you to review between 2–5 systematic reviews per year. The peer review process takes place throughout the year, and our turnaround time for each review is 10–14 days. In return peer reviewers receive free access to **BMJ Clinical Evidence** for 3 months for each review.

If you are interested in becoming a peer reviewer for **BMJ Clinical Evidence**, please complete the peer review questionnaire at www.clinicalevidence.com/ceweb/contribute/peerreviewer.jsp
