\section*{ABSTRACT}

\textbf{Background:} \textit{Pseudomonas aeruginosa} is the most common bacterial pathogen in patients with cystic fibrosis (CF). Current infection control guidelines aim to prevent transmission via contact and respiratory droplet routes and do not consider the possibility of airborne transmission. It was hypothesised that subjects with CF produce viable respirable bacterial aerosols with coughing.

\textbf{Methods:} A cross-sectional study was undertaken of 15 children and 13 adults with CF, 26 chronically infected with \textit{P aeruginosa}. A cough aerosol sampling system enabled fractioning of respiratory particles of different sizes and culture of viable Gram-negative non-fermentative bacteria. Cough aerosols were collected during 5 min of voluntary coughing and during a sputum induction procedure when tolerated. Standardised quantitative culture and genotyping techniques were used.

\textbf{Results:} \textit{P aeruginosa} was isolated in cough aerosols of 25 subjects (89%), 22 of whom produced sputum samples. \textit{P aeruginosa} from sputum and paired cough aerosols were indistinguishable by molecular typing. In four cases the same genotype was isolated from ambient room air. Approximately 70\% of viable aerosols collected during voluntary coughing were of particles \textless{} 3.3 \textmu{}m aerodynamic diameter. \textit{P aeruginosa}, \textit{Burkholderia cepacia} complex and other bacteria may occur in addition to other modes of transmission. The relative contribution of the airborne route may be opportunistic in nature and occur in certain circumstances, such as in enclosed spaces with favourable ambient temperature and humidity as may occur in hospital, clinic and congregate settings.

Particle size distribution of aerosols is a key determinant for both deposition in the respiratory tract and for the ability of particles to remain airborne. To our knowledge, the particle size distribution of aerosols from patients with CF has never been reported. We hypothesised that, during voluntary coughing and during sputum induction, subjects with CF produce viable bacterial aerosols that are respirable. To test this hypothesis we modified a cough aerosol sampling system (CASS) recently developed to measure cough-generated aerosols from patients with \textit{Mycobacterium tuberculosis}.14

Our primary aim was to determine the concentration and particle size distribution of cough aerosols containing culturable \textit{P aeruginosa} and other Gram-negative bacteria of respirable size range, suggesting the potential for airborne transmission.

\textit{Pseudomonas aeruginosa} is the most common bacterial pathogen in patients with cystic fibrosis (CF).1 The prevalence of chronic \textit{P aeruginosa} increases with age, and is a major predictor of mortality and morbidity.2 It is unclear to what extent cross-infection of \textit{P aeruginosa} between patients with CF occurs.3,4 While siblings with CF can harbour the same \textit{P aeruginosa} strain, it was thought until recently that most patients had their own individual strain acquired from the environment.5 With the advent of molecular typing methods there is now convincing evidence of clonal \textit{P aeruginosa} infection in patients attending some paediatric and adult CF centres.6,7 \textit{P aeruginosa} has been cultured from soap holders held at up to 40 cm from the mouth of coughing patients with CF, supporting large respiratory droplet spread.8 The exact mechanisms involved in the spread of bacteria in CF clinics remain unclear.6,7 Two studies have isolated clonal \textit{P aeruginosa} during environmental air sampling up to 10 m from patients with CF infected with clonal strains while performing physiotherapy and lung function testing, suggesting the potential of person-to-person spread via the airborne route.9,10

Current guidelines for infection control for patients with CF recommend only contact and droplet precautions—that is, focusing on hand hygiene and avoiding close contact between patients with CF who are advised to maintain a distance of at least 1 m from other patients.11,12 It is possible that airborne transmission of \textit{P aeruginosa}, \textit{Burkholderia cepacia} complex and other bacteria may occur in addition to other modes of transmission.13 The relative contribution of the airborne route may be opportunistic in nature and occur in certain circumstances, such as in enclosed spaces with favourable ambient temperature and humidity as may occur in hospital, clinic and congregate settings.

Particle size distribution of aerosols is a key determinant for both deposition in the respiratory tract and for the ability of particles to remain airborne. To our knowledge, the particle size distribution of aerosols from patients with CF has never been reported. We hypothesised that, during voluntary coughing and during sputum induction, subjects with CF produce viable bacterial aerosols that are respirable. To test this hypothesis we modified a cough aerosol sampling system (CASS) recently developed to measure cough-generated aerosols from patients with \textit{Mycobacterium tuberculosis}.14

Our primary aim was to determine the concentration and particle size distribution of cough aerosols containing culturable \textit{P aeruginosa} and other Gram-negative bacteria of respirable size range, suggesting the potential for airborne transmission.

\section*{METHODS}

\textbf{Subjects}

Subjects with CF were recruited from both the inpatient and outpatient services at the Royal

Children’s Hospital and The Prince Charles Hospital in Brisbane, Australia. Inclusion criteria were age >9 years, a confirmed diagnosis of CF and culture of P. aeruginosa or B. cepacia complex from sputum on at least one occasion within the previous 12 months. Exclusion criteria included known pregnancy, pneumothorax within the previous 6 months, history of cough syncope or vomiting associated with coughing. After the first subject experienced recurrence of mild haemoptysis during the cough study, we excluded those with haemoptysis in the previous 7 days. Subjects were excluded from hypertonic saline inhalation if there was a history of intolerance of hypertonic saline, presence of asthma symptoms or a forced expiratory volume in 1 s (FEV1) <40% predicted and no previous trials of hypertonic saline. Subjects were asked to withhold all nebulised therapy for 12 h prior to testing.

Cough aerosol sampling system (CASS)
The equipment used was a modification of that developed previously.14 In brief, a subject coughs through a mouthpiece connected to afferent tubing into a chamber whereupon a vacuum pump draws exhaled air and generated respiratory particles through one of two Andersen six-stage impactors. Each stage has 400 holes of decreasing diameter through which appropriately-sized aerosolised particles will penetrate and deposit on an agar plate. A “settle plate” of the same agar at a lower stage has 400 holes of decreasing diameter through which particles (droplets) would be expected to deposit in the afferent tubing, the settle plate and the walls of the chamber. Additional details are provided in the online data supplement.

CASS protocol
The Andersen impactors were loaded with agar plates at room temperature. The tubing from the vacuum pump was attached to the port for the first six-stage impactor in the CASS. After the first session of coughing, the tubing was moved to the second sampler. All unused ports were occluded with plastic tape.

Subjects were instructed to cough into the CASS as frequently and as strongly as was comfortable for 5 min. At the onset of coughing the timer (set for 5 min) controlling the power to the vacuum pump was started. Cough strength was assessed as strong, moderate or weak and cough frequency was assessed quantitatively.

If hypertonic saline could be tolerated, the first sampling was done during voluntary coughing and the second 5-minute sample was collected during inhalation of 5 ml 4.5% saline delivered by a handheld ultrasonic nebuliser (Microneb Alersearch distributed by Becton Dickinson, North Ryde, Australia). Subjects were pretreated with albuterol metered dose inhaler (88 μg per puff), 4 puffs via spacer (Volumatic, Allen & Hanburys, UK). If hypertonic saline was not considered safe, sampling was done with the subject using tidal breathing for 5 min. Sputum samples were collected if produced.

Clinical parameters
Pulmonary function testing
Forced expiratory volume in 1 s (FEV1) and forced vital capacity (FVC) were obtained according to standard guidelines prior to the cough study.15 Respiratory muscle strength was assessed using maximum inspiratory pressure (MIP) and maximum expiratory pressure (MEP) (Morgan Pmax) at the paediatric centre and using a Micro Medical Respiratory Pressure Meter (Micro Medical, Rochester, UK) at the adult centre.

Other
Age, gender, presence of current exacerbation of disease, height, weight and body mass index were recorded.

Room air sampling and air exchange
Using a centrifugal air sampler, two samples were obtained before each cough aerosol study: one during the subjects’ performance of spirometry and one during the cough aerosol study. The indoor air temperature and relative humidity were measured with a thermohygrometer (Rotronic HygroPalm 2, Rotronic Instrument Corp, Huntington, New York, USA) at the beginning of each study. Effective air exchange rates in the consultation rooms used for CASS testing and in the pulmonary function laboratory at the adult centre were determined using carbon dioxide as a tracer gas. Further details are provided in the online supplement.

Microbiology
CASS aerosol samples and chamber settle plate
Cultures were performed using chocolate bacitracin (500 μg/ml) agar in aerobic conditions at 35°C. After 48 h and 72 h incubation, a colony forming unit (CFU) count was performed on each plate including individual colonial P. aeruginosa morphotypes and the combined total CFU count of P. aeruginosa and other Gram-negative bacteria. Following presumptive screening (characteristic colonial appearance, presence of oxidase and growth at 42°C), the identity of each P. aeruginosa isolate was confirmed by species-specific oprL gene PCR.16 Other non-fermenting Gram-negative bacteria detected throughout the study were identified using a combination of API 20NE (bioMerieux), amplified rDNA restriction analysis (ARDRA) and recA-based PCR analysis.17 18

Each Andersen sampler stage contains 400 holes and each CFU is regarded as the result of an infectious particle within a specific size range impacting on the agar. Colony counts exceeding 400 have been interpreted in two ways: an accepted “positive-hole” correction model taking into account the probability of multiple hits through each hole and a conservative model of a maximum count of 400 only.15 20 The total sum of P. aeruginosa or B. cepacia complex colonies counted (total count) in all the Andersen stages for 5 min of voluntary coughing and for 5 min hypertonic saline study or tidal breathing was calculated, as was the sum of the colonies from stages 4, 5 and 6 (<3.3 μm, termed “small aerosol fraction”).

Sputum samples, afferent limb cultures and air samples
Standard quantitative culture methods were used.21 For air samples and afferent limb cultures, only Gram-negative non-fermentative bacteria were assessed. Isolates were identified as above with molecular strain typing of P. aeruginosa isolates. Further details are provided in the online data supplement.

Analysis of data
Counts for individual components and the totals for Andersen stages 1–6 (total) and for Andersen stages 4–6 (small fraction) were logarithmically transformed before analysis to correct for skewness. Means and 95% confidence limits (95% CI) were back transformed from log to linear scales for presentation. The paired differences between counts during voluntary coughing and each of the hypertonic and tidal breathing studies were analysed by paired t tests and mean differences were also back transformed from log to linear scales to calculate the ratios of counts during voluntary coughing and each of the hypertonic
and tidal breathing studies. Correlation coefficients were estimated between logarithmically transformed total counts and clinical and demographic factors where available for all subjects. The Fisher exact test was used for the association between positive air samples and high total counts. All reported p values are two-sided. Linear regression was used to estimate the slope of the relationship between FEV$_1$ and total count. All analyses were performed with SPSS software Version 15.

RESULTS

CASS studies

Twenty-eight subjects (15 children, 13 adults) were consecutively recruited and completed 5 min of voluntary coughing. Twenty subjects were administered nebulised hypertonic saline and seven subjects had measurements during tidal breathing. One subject performed the voluntary cough only. Thirteen subjects were studied during a pulmonary exacerbation (table 1).

Sputum microbiology

In the 12 months before the study, 27 subjects had sputum that cultured positive for \textit{P. aeruginosa} and one subject had cultured \textit{B. cenocepacia} (table 2). Of the 27 patients with \textit{P. aeruginosa} infection, all adults (n = 12) and 14 children had chronic infection based on the Leeds criteria.\textsuperscript{22} One child had recently cleared a new infection with \textit{P. aeruginosa} following an eradication course of antibiotic therapy and cultured normal respiratory flora from a sputum sample collected on the day of testing. The patient with \textit{B. cenocepacia} had chronic infection based on the Leeds criteria (table 2).\textsuperscript{22} On the study day, 23 subjects provided expectorated sputum samples. Of these, one subject grew \textit{B. cenocepacia} as expected and \textit{P. aeruginosa} was cultured in 21. In six subjects \textit{Staphylococcus aureus} was cultured and in two methicillin-resistant \textit{S. aureus} was cultured. Other organisms cultured from sputum included \textit{$\alpha$-haemolytic streptococci, Aspergillus species} and yeasts. Molecular strain typing demonstrated a common clone corresponding to the previously described Australian Epidemic Strain 2 (AES2) in 16 subjects (6 adults, 10 children) and 5 had unique strains (4 adults, 1 child) (table 2).\textsuperscript{23}

CASS microbiology

Of the 28 subjects, 25 had cough aerosols that grew \textit{P. aeruginosa}. One subject cultured \textit{P. aeruginosa} from cough aerosols only with the hypertonic saline study and not from voluntary coughing. One subject cultured \textit{B. cenocepacia} from cough aerosols. Two subjects had no Gram-negative bacteria cultured from cough aerosols. In five subjects with cough aerosols with \textit{P. aeruginosa}, additional Gram-negative bacteria were co-cultured (\textit{Stenotrophomonas maltophilia} in four and \textit{Achromobacter xylosoxidans} in one, table 2). Two of the subjects who co-cultured \textit{S. maltophilia} did not produce sputum and sputum culture was negative for \textit{S. maltophilia} for the other two. Three of the four subjects cultured \textit{S. maltophilia} intermittently from sputum at other times. The subject with \textit{A. xylosoxidans} in the cough aerosol culture did not culture the organism in the sputum sample on this occasion, although the subject was known to be chronically infected with this organism which had been cultured repeatedly from previous sputum samples.

The corrected total count of CFUs obtained from generated aerosols varied widely among subjects and was log normally distributed (voluntary cough: range 0–13 485 CFU, fig 1). All subjects but one who cultured \textit{P. aeruginosa} in sputum also cultured \textit{P. aeruginosa} of identical genotype in the CASS cough aerosols. The total count from sputum correlated with the total corrected count for voluntary coughing from the aerosols (r = 0.58, p = 0.008). Three of the seven subjects who had tidal breathing studies had positive CASS aerosol cultures, with \textit{P. aeruginosa} cultured in low numbers (total aerosol counts from tidal breathing 1, 5 and 137 CFU).

Settle plate and air sampling microbiology

The chamber settle plate and afferent limb equipment was not changed between the two components of the study for individual subjects with quantitative culture, reflecting large droplet deposition for both components of the study combined. The mean total count for the settle plate was 6 CFU (95% CI 3 to 14). The mean total count for the afferent limb was 56 CFU/ml wash fluid (95% CI 10 to 303).

Mean (SE) air exchange rates ranged between 9.77 (0.06) and 19.40 (0.70) exchanges per hour in the testing rooms. A total of 101 air samples were collected before and during testing. Sixteen samples cultured unique strains of \textit{P. aeruginosa} during testing of 14 patients. The unique strains isolated did not match any sputum or CASS isolates. Five air samples cultured AES2 strain during testing of four subjects with AES2 strain of \textit{P. aeruginosa}. For these four subjects, sputum, cough aerosol and air samples all cultivated the same strain. Three of the AES2 positive air samples were collected during pulmonary function testing and two during background testing in the CASS study rooms. Positive air samples were associated with a high concentration in cough aerosols. If only subjects with AES2 were considered, four out of five subjects with total cough aerosol counts

AES2, Australian Epidemic Strain 2; CASS, cough aerosol sampling system.

Five subjects also cultured additional Gram-negative bacteria in cough aerosols (4 Stenotrophomonas maltophilia and 1 Achromobacter xylosoxidans).

>1000 CFU had positive air samples and no subjects out of the 10 with lower total CFU counts had positive air samples (p = 0.005). Temperature and humidity did not vary significantly between study sites or study days at each site (data not shown).

**CASS microbiology: voluntary cough, hypertonic cough and tidal breathing**

The infective particle size distribution of cough aerosols of *P. aeruginosa* or *B. cepacia* during voluntary coughing is shown in fig 2. Using the corrected total counts, 71.8% of particles (95% CI 66.8% to 76.8%) containing culturable aerosol isolated from voluntary coughing were on Andersen stages 4, 5 and 6 of the Andersen samplers (small aerosol fraction ≤3.3 μm). The conservative model gave similar results with 69.9% (95% CI 64.6% to 75.4%) in the small aerosol fraction. Mean total corrected counts were much lower during tidal breathing (2, 95% CI 0.5 to 15) than during voluntary coughing (85, 95% CI 28 to 238; p < 0.001) or hypertonic saline (68, 95% CI 21 to 215). There was no significant difference in total corrected counts between voluntary coughing and hypertonic saline (p = 0.12). The pattern of differences was unaffected by using the conservative model (data not shown).

**CASS microbiology: clinical correlates**

FEV1 correlated with the total corrected count from the voluntary cough aerosol (r = 0.45, p = 0.019; fig 3) and also with the corrected small aerosol fraction (r = 0.45, p = 0.018). Similarly, FEV1 correlated with the conservative total count (r = 0.59, p = 0.044) and conservative small aerosol fraction (r = 0.39, p = 0.047) during voluntary coughing. There was no significant association between cough aerosol CFU counts and any other clinical factor including gender, age, testing at paediatric or adult centre, current exacerbation status, FVC, MIP, MEF, percentage predicted FEV1, presence of clonal *P. aeruginosa*, quality or actual number of coughs counted (data not shown). There was a trend for an association of peak expiratory flow (r = 0.36, p = 0.079) and of body mass index (r = 0.37, p = 0.058) with total corrected count for voluntary coughing.

**DISCUSSION**

This is the first study to report the magnitude, variability and particle size distribution of culturable aerosols of Gram-negative bacteria produced by coughing in patients with CF. Although there is evidence of culturable Gram-negative bacteria in the large droplets within the afferent tubing and settle plates in the cough chamber, a large proportion of culturable particles were found to be in a size range that is likely to deposit in the lower respiratory tract. Genetically indistinguishable bacteria were identified in expectorated sputum and in the cough-generated aerosols, and in four experiments the same organisms were also isolated from the ambient room air. This supports the assertion that the sources of the bacteria are the patients rather than the hospital or nearby environment.

Aerosolisation of respiratory tract particles during coughing and sneezing and even during tidal breathing is a well recognised phenomenon associated with the spread of many infections including measles, influenza and tuberculosis. The majority of respiratory pathogens have been thought to be spread by large droplets that settle within an approximate 1 m range of an individual, providing a low risk of airborne infection. Infection control practices for most CF centres reflect recently published infection control guidelines suggesting that patients should maintain a distance of at least 1 m to reduce the risk of cross-infection. The risk of acquisition of infection from respiratory aerosols is complex and probably relates to the pathogen type, concentration of the organism in the aerosol, the susceptibility of exposed individuals and the environment (air movement, relative humidity, temperature, etc). Limited studies have examined particle size distribution of respiratory aerosols and most have reported large droplet formation, predominantly particles with a diameter of >8 μm. More recently, Papineni and Rosenthal reported that 85% of particles were <1 μm and that coughing produced more aerosol particles than did breathing or talking. The first published study to use a CASS examined patients with tuberculosis and, like our study, found that most of the respiratory particles were <3.3 μm. Our study shows that patients with CF produce culturable aerosols in a wide range of particle sizes including both respiratory
CF centres in the UK, Europe and Australia has suggested cross-
identification of genetically related 
P aeruginosa 
bacteria. Infection may result from direct inhalation of aerosolised 
spreaders' (eg, in severe acute respiratory syndrome).32 33 
Patients as 'disseminators' (eg, in tuberculosis) or 'super-
distribution is consistent with descriptions of highly infectious 
cough aerosols with a log normal distribution. Such a 
deposition in the respiratory tract for 
P aeruginosa 
contaminating the air close to patients with the same infection 
during physiotherapy or lung function testing have been 
reported.7 Our results provide further evidence that cross-
 infection may result from direct inhalation of aerosolised 
bacteria. 

This study demonstrates widely varying bacterial counts in 
cough aerosols with a log normal distribution. Such a 
distribution is consistent with descriptions of highly infectious 
patients as ‘disseminators’ (eg, in tuberculosis) or ‘super-
spreaders’ (eg, in severe acute respiratory syndrome).32 33 
Factors influencing the extent of isolation of Gram-negative 
bacteria in cough aerosols are likely to be complex, including 
both host factors and bacterial factors such as enhanced survival 
in air. Our data show that the concentration of bacteria in the 
sputum and the forced expiratory flow rates were related to 
cough aerosol concentration, with a trend for association with 
higher peak flow and higher body mass index. These data 
suggest that patients with milder lung disease, perhaps as a 
result of stronger cough, may have an increased risk of 
producing infectious aerosols. This warrants further investiga-
tion as the improvement in clinical outcomes in patients with 
CF may potentially increase the risk of spread of clonal strains 
of 
P aeruginosa 
and other Gram-negative bacteria. 

The only air samples that cultured 
P aeruginosa 
which matched clinical samples from sputum or CASS samples were 
clonal AES2 strains. Given that patients who had positive air 
samples also had high total aerosol counts, we were unable to 
determine if the density of infection on its own—or whether, in 
addition, the nature of the specific infection—contributed to 
the positive air samples. The source of the 
P aeruginosa 
air isolates that did not match any clinical samples is unknown and 
environmental sampling of surfaces was not undertaken. It is 
possible that environmental sources such as sinks may have 
been involved as hand washing occurred during testing. The 
measured air exchange rates in the study rooms provide an 
important perspective as air sampling was performed for 12 min 
on each occasion and, during this period, 2–4 complete air 
exchanges occurred. Higher rates and density of positive air 
samples may be anticipated in less well ventilated rooms. 

Nebulised hypertonic saline is now recognised as improving 
mucociliary clearance.34 We sought to determine if hypertonic 
saline-induced cough further enhanced the production of 
bacterial aerosols, but we found similar results to those seen 
with voluntary coughing and much greater than those obtained 
during tidal breathing. Treatments such as physiotherapy, 
mucolytic agents and even nebulised antibiotics which can 
induce coughing are likely to result in similar cough-induced 
aerosols as with voluntary coughing. Although only seen in 
three of seven patients tested during tidal breathing, the 
presence of 
P aeruginosa 
in the cough aerosols and in the small aerosol fraction from two patients warrants further study as 
any reassessment of infection control recommendations to 
incorporate the role of airborne transmission may not only 
apply to coughing patients. 

The significance of aerosol-positive sputum-negative results 
for isolation in low numbers of 
S maltophila 
(n = 2) and 
A xylooxidans 
(n = 1) is uncertain, but it is possible that separating 
respiratory particles by size negates the obscuring of individual 
colony morphotypes by other flora which may occur with direct 
sputum culture. 

There are several limitations to this study. First, the study 
was not powered to examine the effects of many of the clinical 
variables such as exacerbations or strain of 
P aeruginosa 
on the production of cough aerosols. In particular, there were few 
patients with unique strains of 
P aeruginosa 
and none who produced high concentrations of cough aerosols. The association 
between a specific strain and obtaining a positive air sample 
could not therefore be determined. Second, the media in the 
Andersen plates was selective for Gram-negative organisms and 
thus it is not possible to generalise these results to patients with 
CF infected with Gram-positive bacteria, mycobacteria or fungi. 
Third, we did not perform reproducibility or efficiency studies of the 
CASS. Fourth, the studies of tidal breathing were in a
select group of patients who did not undertake hypertonic saline-induced cough studies and further work is required to evaluate the extent to which tidal breathing is associated with the generation of potentially infective particles. Finally, while this study provides evidence that patients with CF and Gram-negative infection can produce potentially infectious cough aerosols, we cannot draw conclusions about transmission to susceptible individuals. A recent study examined the survival of P aeruginosa in vitro and found bacterial survival, at least for a limited time period of <90 s, to be favoured by lower temperature and mucoid phenotype.\(^a\) While providing further evidence that airborne transmission is plausible, transmission by this route is yet to be proved beyond doubt.

In conclusion, this study shows that patients with CF infected with P aeruginosa can produce respirable infectious cough aerosols in a wide range of concentrations of a log normal distribution. We also detected other non-fermenting Gram-negative bacteria including B cenocepacia in the small aerosol fraction, suggesting that airborne transmission of such organisms is biologically plausible. Further studies of potential airborne transmission of bacterial pathogens in patients with CF are warranted to provide a scientific basis for infection control recommendations to prevent the spread of multidrug-resistant or clonal strains of P aeruginosa and other Gram-negative bacteria in this patient population.
