Sweat gland bioelectrics differ in cystic fibrosis: a new concept for potential diagnosis and assessment of CFTR function in cystic fibrosis

T Gonska,1,2 W Ip,2 D Turner,3 W S Han,4 J Rose,2 P Durie,1,2 P Quinton4,5

ABSTRACT

Background: For nearly 50 years the diagnosis of cystic fibrosis (CF) has depended on measurements of sweat chloride concentration. While the validity of this test is universally accepted, increasing diagnostic challenges and the search for adequate biomarker assays to support curative-orientated clinical drug trials have created a new demand for accurate, reliable and more practical CF tests. A novel concept is proposed that may provide a more efficient real-time method for assessing CFTR function in vivo.

Methods: Cholinergic and β-adrenergic agonists were iontophoresed to stimulate sweating. The bioelectric potential from stimulated sweat glands (SPD) was measured in vivo using a standard ECG electrode applied to the skin surface. SPD and sweat chloride concentrations were compared in cohorts predicted to express a range of CFTR function as presented by healthy controls (HC), heterozygotes (Hz), pancreatic sufficient (CFPS) and pancreatic insufficient patients with CF (CFPI).

Results: The median SPD was hyperpolarised in patients with CF compared with control subjects (−47.4 mV vs −14.5 mV, p < 0.001). In distinguishing between control and CF subjects, SPD (area under receiver operator curve (AUC) = 0.997) was similar to sweat chloride concentration (AUC = 0.986). Sequential cholinergic/β-adrenergic sweat stimulation dramatically depolarised the SPD in patients with CF (p < 0.001) but had no effect in control subjects (p = 0.6) or on the sweat chloride concentration in either group (p > 0.5). Furthermore, the positive SPD response was larger in CFPI than in CFPS subjects (p = 0.04).

Conclusion: These results support the concept that skin surface voltages arising from stimulated sweat glands can be exploited to assess expressed CFTR function in vivo and may prove to be a useful diagnostic tool.

Cystic fibrosis (CF) is the most common inherited and life-shortening disorder in the Caucasian population. Defective epithelial chloride channel function due to mutations in the cystic fibrosis transmembrane regulator (CFTR) gene affects secretory and absorptive organs leading to progressive lung disease as a major factor for morbidity and mortality, pancreatic insufficiency, gastrointestinal complications and infertility.4 The pathognomonic hallmark of high sodium chloride concentrations in sweat from patients with CF formed the basis of the classic sweat test which was developed 50 years ago.5

The defect in CFTR chloride channels also results in an altered bioelectrical potential in the CF sweat duct that is approximately tenfold more negative than normal.5 Similar though less pronounced observations in airway epithelia led to the introduction of measurements of nasal potential differences (NPD) as an alternative functional diagnostic test for CF.6,7 However, performance of the NPD is technically demanding as well as negatively influenced by inflammation and by exposure to irritants such as cigarette smoke.8,9 Not only are sweat glands one of the richest sources of CFTR chloride channels, but they are arguably the most assessable of affected CF organs. Moreover, in contrast to most other affected organs, sweat glands are not altered by secondary pathologies associated with ductal plugging and inflammation.10 We therefore explored the possibility of assessing the difference in the bioelectric properties of sweat glands in vivo by designing a novel diagnostic assay for CF and other diseases10 that may offer advantages in economy and simplicity to facilitate diagnoses in less developed settings. We also note the present need for biomarkers to assay new drugs, some of which are now being tested in early phase clinical trials.11–12

The need for real-time easily executed outcome measures of the function of CFTR seems likely to increase as multiple clinical sites and larger numbers of subjects enter later phases of trials that require definitive markers of molecular function.13–14

In this proof of concept study we introduce a novel technique to assess CFTR function in vivo by measuring the transudtactal voltage of sweat glands at the skin surface (SED) as a new diagnostic parameter as well as a possible assay for monitoring changing levels of CFTR function in therapeutic trials. We first define the ability of cholinergically-stimulated SFDs to segregate cohorts of healthy controls (HC) and heterozygote carriers (Hz) from pancreatic-sufficient patients with CF (CFPS) and pancreatic-insufficient patients with CF (CFPI). We then present evidence that additional β-adrenergic stimulation might further improve the diagnostic power of this novel method among cohorts predicted to express a range of CFTR function.

METHODS

Study participants

Between July 2006 and December 2007 we prospectively and consecutively ascertained 10 HC, 10 Hz, 10 CFPS and 8 CFPI. The diagnosis for CF as well as the exocrine pancreas status was previously established according to current diagnostic criteria.15–16 Study subjects were selected based on their previous participation in a large diagnostic study, including HC, providing us with
extended clinical, functional and genetic information. All study participants signed informed consent and underwent test protocols on at least two occasions.

**Sweat stimulation**

Sweat secretion was stimulated using the cholinergic agent pilocarpine 1% (USP grade, Spectrum, Gardena, USA) applied by iontophoresis for 5 min to the volar surface of the forearm (Protocol 1). In a second assay at an adjacent skin site we iontophoresed pilocarpine (1%) as before, but immediately followed this cholinergic stimulation by iontophoresing into this same area a combination of the β-adrenergic agent isoproterenol (1%) and the phosphodiesterase inhibitor aminophylline (0.8%; USP grade, Spectrum, Gardena, USA and AC2C, Montreal, Canada) (Protocol 2). Drugs were dissolved in distilled water immediately before use. The β-adrenergic solution was acidified to pH 3.0 with HCl to protonate the drugs for maximal transdermal iontophoretic delivery.

To minimise hyperaemia of the skin often seen with the standard quantitative pilocarpine iontophoresis test (QPIT) (50 μA/cm² is recommended as standard operating procedure for the QPIT) and possible trauma to the underlying sweat glands,11 12 we first determined the iontophoresis current needed for a maximised SPD response in 15 additional control subjects (mean age 54.6 years, range 22–60). Maximal SPD and sufficient sweat volumes for chemical analysis were obtained with an applied iontophoresis current of 50 μA/cm², which was therefore used in all subsequent experiments (fig 1).

**Sweat chloride concentration**

Sweat chloride concentration was determined by digital chloride meter (LabConco Corporation, Kansas City, Missouri, USA) from sweat collected in the Macroduct collector cup system (Wescor, Logan, USA) with a minimum volume of 20 μl.

**Sweat gland potential difference (SPD) measurements**

After stimulation the skin area was gently cleaned with distilled water and carefully blown dry. Water-saturated mineral oil was applied to the stimulated area to maximise SPDs by minimising transdermal current shunts. An ECG electrode (ConMed, Utica, US) presoaked in 3 M KCl for 30 min was taped securely over the prepared area. An angiocath (G22) was inserted subcutaneously by needle puncture. The steel needle was removed and the plastic infusion line was filled with sterile 0.9% NaCl solution. The infusion line was then bridged via plastic tubing filled with 3 M KCl to an Ag/AgCl reference electrode. The SPD was measured as the voltage between the ECG electrode and the subcutaneous reference electrode using a voltmeter (Digital Multimeter, ET1039, input impedance 10⁶ ohms). The SPD was recorded every minute for 30 min after sweat stimulation. As shown in fig 2, SPD measurements hyperpolarised with time, reaching a plateau 20–30 min after stimulation. An average of the last five minute SPD recordings (minutes 26–30) was used for data analysis.

**Electrode asymmetry and drift**

Before and after each test the asymmetry between the reference and the ECG electrode for SPD measurements was assessed by applying the ECG electrode and the infusion line to a 0.9% NaCl-soaked sponge. Property differences between the ECG and reference electrode, as well as variability between each ECG electrode, apparently resulted in some electrode asymmetry and drift. Data from any electrodes with >±5.0 mV absolute asymmetry or drift were excluded. The final asymmetry was subtracted from each SPD before further analysis.

**Statistical analysis**

Data were summarised as medians with interquartile ranges (IQR, 25th to 75th percentile). Missing data are explained as exclusion of SPD measurements due to asymmetry >±5.0 mV or unavaiable sweat chloride concentration due to insufficient sweat volume. Non-parametric tests (Wilcoxon rank-sum test and Kruskal-Wallis test) were used for comparison between the groups. Analysis for diagnostic test accuracy was performed by determining the area under a receiver-operator characteristic curve (AUC) with its corresponding 95% confidence interval (CI). An AUC of >0.7 was considered as indicative of “fair” discriminative ability, 0.8 as “good” and >0.9 as “excellent”.

For reliability analysis, two repeated tests in each individual were compared using the 95% limits of agreement described by Bland and Altman.13 For all comparisons, two-tailed tests for a p value of <0.05 were applied to determine significant differences. Graphs and analyses were performed with Prism Version 4.0 (GraphPad Software, 2003) and SPSS Version 16.0, Graduate Student Version, SPSS Inc, 2007.

**RESULTS**

The study subjects are described in table 1. The groups were not sex matched. The mean (SD) ages of the HC (29.7 (8.5) years) and the CFPI (29.9 (4.7) years) cohorts were less than of the Hz...
Cystic fibrosis

sweat gland SPDs were significantly hyperpolarised in the CF group compared with the control group (−47.4 mV vs −14.5 mV, p < 0.001). In an area immediately adjacent to the SPD measurement site, sweat was collected for determination of chloride concentration. The sweat chloride concentration was also significantly higher in the CF group than in the control group (98.5 mmol/l vs 21.5 mmol/l, p < 0.001). Table 2 shows the SPD and sweat chloride concentration data for all groups.

SPD compared with sweat chloride concentration

The power of the SPD assay to distinguish between different groups was comparable to that of the sweat chloride assay (table 2, fig 3). Both assays were plotted in relation to each other, revealing good correlation of SPD to sweat chloride concentration obtained simultaneously (r = −0.7, 95% CI −0.84 to −0.48, p < 0.001; fig 4). Furthermore, using ROC as an analytical tool, SPD was found to have a similar accuracy to sweat chloride concentration in identifying patients with CF, with equal excellent AUC of 0.997 (95% CI 0.988 to 1.007) for SPD and 0.986 (95% CI 0.958 to 1.014) for sweat chloride concentration (fig 4).

Neither sweat chloride concentration nor cholinergically-stimulated SPD resulted in a significant difference between HC and Hz (p = 0.7 and p = 0.6, respectively) or between CFPS and CFPI (p = 0.2 and p = 0.5, respectively).

For 31 of 37 study subjects, repeated SPD and sweat chloride measurements were available (fig 4). Analysing the differences between test and retest results by the Bland-Altman method, sweat chloride concentration showed better repeatability for most patients with CF (values >40 mmol/l), whereas equal but higher variability was seen for SPD throughout the whole functional spectrum. However, there was no fixed or proportional bias for either test and the 95% confidence limits of agreement were comparable. Despite the wider difference between two tests seen for SPD in some study subjects, the second SPD test did not alter the classification of individuals in their subgroup (table 2).

CFPI, pancreatic-insufficient CF patients; CFPS, pancreatic-sufficient CF patients; HC, healthy controls; Hz, heterozygotes. CFTR gene sequencing was performed for all subjects.22-26
SPD after sequential cholinergic/β-adrenergic stimulation

In an attempt to directly activate CFTR chloride channels and improve the segregation of subgroups, we modified the sweat stimulation protocol using sequential stimulation with cholinergic followed by β-adrenergic agonists (Protocol 2). Interestingly and unexpectedly, sequential stimulation with cholinergic and then β-adrenergic agonists had no effect on median SPD in HC and Hz as control group (p = 0.6), but significantly depolarised the SPD of all patients with CF (p < 0.001, fig 5). Sweat chloride concentration did not change in either group following sequential stimulation (HC/Hz: p = 0.95; CFPS/CFPI: p = 0.94; fig 5).

Calculating the difference of the SPD response between cholinergic and sequential cholinergic/β-adrenergic stimulation (ΔSPDchol/β-adren), we found a statistically significant difference between controls and patients with CF (p < 0.001). After sequential stimulation neither the SPD of HC nor Hz subjects changed significantly, whereas the SPD of CFPS and CFPI patients was significantly depolarised with both agonists. Thus, subgroup analysis showed no statistical difference between the response of HC and Hz (p = 0.5). However, SPD was significantly more positive in CFPI patients following sequential cholinergic/β-adrenergic sweat stimulation than in CFPS patients, so that ΔSPDchol/β-adren between CFPS and CFPI was significantly different (p = 0.04; table 2, fig 5).

Adverse events

No severe systemic or local adverse events were observed. About 20% of the study subjects showed very mild transient reddening of the skin following iontophoresis. One subject had a moderate skin reaction (reddening) which resolved after 30 min.

DISCUSSION

A novel sweat test

For over 50 years the gold standard test in CF has been the QPIT which involves a multistep procedure of (1) in vivo stimulation of the sweat glands; (2) collection of the sweat secretion; and (3) laboratory determination of the sweat chloride concentration. 24 We have now explored the increased

**Figure 3** Comparison of sweat gland potential difference (SPD) and sweat chloride concentration ([Cl⁻]) measurements. Each subject underwent simultaneous SPD and sweat chloride measurements; (n) number of subjects. Scatter plots show (A) the average of SPDs recorded during the last 5 min after stimulation and (B) the sweat chloride concentration for each individual in each group. SPD and sweat chloride concentrations show significantly different medians between the control and patient groups (p < 0.001). HC, healthy control; Hz, heterozygotes; CFPS, patients with pancreatic-sufficient cystic fibrosis; CFPI, patients with pancreatic-insufficient cystic fibrosis.
negative bioelectric potential arising directly from the basic CF defect to introduce a proof of concept for a new simple practical real-time assay of sweat gland function which appears to be as accurate as the traditional QPIT and, perhaps, with further technical improvement in electrode design, may prove to be more reproducible and sensitive.

The bioelectrical properties of isolated sweat ducts have been extensively studied. Moreover, in vivo measurements in sweat droplets from single glands on the skin showed that the electrical potential of the sweat ducts can be recorded at the gland orifice on the skin surface. We therefore surmised that the electrical potential of the sweat ducts can be recorded at the gland orifice on the skin surface and that the bioelectric potential arising directly from the basic CF defect to introduce a proof of concept for a new simple practical real-time assay of sweat gland function which appears to be as accurate as the traditional QPIT and, perhaps, with further technical improvement in electrode design, may prove to be more reproducible and sensitive.

The bioelectrical properties of isolated sweat ducts have been extensively studied. Moreover, in vivo measurements in sweat droplets from single glands on the skin showed that the electrical potential of the sweat ducts can be recorded at the gland orifice on the skin surface. We therefore surmised that placing an ECG electrode over an area of stimulated skin would measure the average of the electrical potentials from ducts of all secreting sweat glands (>1000) under the electrode. This skin potential could, in turn, serve as a real-time diagnostic measure without further procedures such as chemically analysing sweat. Moreover, since the electrical potential from the sweat duct directly reflects the function of CFTR, this technique might assess the impact of drugs administered in clinical trials for CF without further procedures such as chemically analysing sweat.

SPD as a biomarker assay for CF
In order to establish the usefulness of the sweat gland SPD for assessing CFTR function, we measured phenotypically and genotypically well-characterised cohorts of HC, Hz, patients with CFPS and patients with CFPI. We anticipated that maximally stimulating CFTR in all groups might enhance differences in SPD responses between the different subgroups (fig 3), giving equal diagnostic accuracy to identifying patients with CF (fig 4). This finding must now be confirmed in a larger unselected and more representative population in a future study. The high correlation between SPD and sweat chloride concentration indicates that both methods measure phenomena related to the same defect (CFTR) in sweat glands. Repeatability analysis showed larger variability in the control group for sweat chloride concentration and an overall larger but similar variability in the controls and CF group for SPD measurements. However, the absence of any bias in the Bland-Altman analysis, as well as comparable limits of agreement, suggest acceptable repeatability for SPD measurements. The larger variability in SPD measurements observed in some individuals may be due, at least partly, to reduced sensitivity caused by electrode asymmetries (discussed later) and should be reduced with improvements in electrode design.

Previous studies in a larger cohort showed a slight elevation in mean sweat chloride concentration in Hz compared with HC and a statistically lower mean sweat chloride concentration in patients with CFPS compared with those with CFPI, although the overlap between the groups precluded segregation of individuals. An assay that provides an increased ability to detect differences between subgroups, particular between CFPS and CFPI, based on small increments in CFTR function, may therefore have significant value for assessing degrees of correction achieved by drug therapy to modify mutant CFTR function. However, neither sweat chloride concentration nor cholinergically-induced SPD testing distinguished between HC and Hz or between CFPS and CFPI in this small cohort (fig 3, table 1).

Sequential cholinergic/β-adrenergic sweat stimulations promise to improve diagnostic performance of SPD
We reasoned that maximally stimulating CFTR in all groups might enhance differences in SPD responses between the
subgroups where theoretically, at least, CFTR function is twofold greater in HC than in Hz subjects and is probably greater in patients with CFPS than in those with CFPI. Following cholinergeric sweat stimulation we iontophoresed a mixture of the β-adrenergic agonists isoproterenol and aminophylline to enhance cAMP levels and maximally stimulate CFTR activity. We expected maximal effects, if any, in control subjects where CFTR is highly expressed. However, stimulation with β-agonists did not change the average SPD in either HC or Hz subjects but, surprisingly, increased (depolarised) the SPD response in all patients with CF, with the greatest effect in those with CFPI (fig 5). The differences between the SPD responses following cholinergeric sweat stimulation alone and sequential cholinergeric/β-adrenergic stimulation (ΔSPDchol/β-adren) was not only significantly different between controls and patients with CF (p < 0.001), but also between CFPS from CFPI (p = 0.04). In fact, the ΔSPDchol/β-adren linearly correlated with the measured base-Chloride concentration in the same subject. (A) SPD values remained relatively constant for healthy controls and heterozygotes, but depolarised markedly in all CF patients. (B) The sweat chloride values were not detectably altered in any group. Box plots show medians and IQR of the difference between chol and β-adren-induced SPD responses (ΔSPDchol/β-adren). (C, D) Not only are the ΔSPDchol/β-adren changes significantly different for patients compared with control groups (*p = 0.04), but the amount of depolarisation is significantly less in CFPS patients than in CFPI patients (**p = 0.04). HC, healthy control; Hz, heterozygotes; CFPS, patients with pancreatic-sufficient cystic fibrosis; CFPI, patients with pancreatic-insufficient cystic fibrosis.

Why does β-adrenergic sweat stimulation depolarise SPD in CF?

While the β-adrenergically unaltered SPD response in controls may be explained by the presence of constitutively fully-activated CFTR in these glands,2 the dramatic depolarisation in patients with CF seems puzzling. We expected that less (or no) CFTR expression in patients with CF would result in smaller (or no) changes in SPD, not larger. Two scenarios might possibly explain these results. First, β-adrenergic activation may stimulate or insert additional mutant CFTR in the membrane which would shunt the electrogenic potentials in these ducts, thus leading to a more positive “normalised” SPD.27 However, increased CFTR conductance should have decreased sweat chloride concentration, which was not observed. Moreover, β-adrenergic stimulation is not known to increase the expression of ΔF508 mutations.

Second, and perhaps more likely, β-adrenergic stimulation appears to stimulate acid secretion by the sweat duct28 29 which should depolarise the lumen and hence the SPD. The presence of a small chloride conductance, as expected for some mutations, would partially shunt this potential, as seen in patients with CFPS, and reduce—but not abolish—the depolarising effect of proton secretion.

Technical challenges of the SPD sweat test

Using a simple ECG set-up for SPD recordings, we have achieved excellent statistical separations. However, artefacts introduced by asymmetries and voltage drifts between the measuring and reference electrodes (>±5 mV in up to 55% of experiments) may account for some of the intra- and inter-individual variability. These errors may have been caused by (1) changes in the composition of the gel of the measuring ECG electrode due to exposure to different volumes and salt concentrations in...
secreted sweat; and (2) use of unmatched electrodes, ECG gel vs agar Ag/AgCl. Improvements in the design of the electrode are expected to minimise these artefacts and increase the accuracy of the SPD recording. Furthermore, to obviate the need for subcutaneous needles in paediatric subjects, other means of establishing an electrical reference with the serosal fluid such as a minor skin abrasion may prove preferable.

In summary, the findings in this paper show, for the first proof of concept, that cholinergically-stimulated SPDs can be used as an immediate, simple and accurate method to assess CFTR function in vivo. Including a second protocol to compare cholinergically-stimulated SPDs with combined cholinergically and β-adrenergically-stimulated SPDs increased the power of the test to detect smaller differences in CFTR function, notably between subjects with CFPS and CFPI. These observations therefore justify further development of the SPD as an outcome parameter in clinical trials and as a diagnostic test for CF.

Acknowledgements: The authors thank all volunteers and especially CF patients for participating in the study; Jennifer Pike, Dr Elzabeth Tullis, Susan Carpenter, Louise Taylor, Felix Ratjen, Douglas Conrad and Mark Plan for patient referral; Dr Christine Bear for her support and advice on test development; Lynda Ellis and Sheelahg Martin for their assistance with the clinical data; Julie Gibson for advice on communication with regulatory authorities; and special thanks to Annie Dupuis for assistance with the statistical analysis.
