ABSTRACT

Background: Host- and pathogen-related factors associated with septic shock in pneumococcal pneumonia are not well defined. The aim of this study was to identify risk factors for septic shock and to ascertain patient outcomes. Serotypes, genotypes and antibiotic resistance of isolated strains were also analysed.

Methods: Observational analysis of a prospective cohort of non-severely immunosuppressed hospitalised adults with pneumococcal pneumonia. Septic shock was defined as a systolic blood pressure of <90 mm Hg and peripheral hypoperfusion with the need for vasopressors for >4 h after fluid replacement.

Results: 1041 patients with pneumococcal pneumonia diagnosed by Gram stain and culture of appropriate samples and/or urine antigen test were documented, of whom 114 (10.9%) had septic shock at admission. After adjustment, independent risk factors for shock were current tobacco smoking (OR, 2.11; 95% CI, 1.02 to 4.34; p = 0.044), chronic corticosteroid treatment (OR, 4.45; 95% CI, 1.75 to 11.32; p = 0.002) and serotype 3 (OR, 2.24; 95% CI, 1.12 to 4.75; p = 0.022). No significant differences were found in genotypes and rates of antibiotic resistance. Compared with the remaining patients, patients with septic shock required mechanical ventilation more frequently (37% vs 4%; p<0.001) and had longer length of stay (11 vs 8 days; p<0.001). The early (10% vs 1%; p<0.001) and overall case fatality rates (25% vs 5%; p<0.001) were higher in patients with shock.

Conclusions: Septic shock is a frequent complication of pneumococcal pneumonia and causes high morbidity and mortality. Current tobacco smoking, chronic corticosteroid treatment and infection caused by serotype 3 are independent risk factors for this complication.

Streptococcus pneumoniae remains a major cause of disease worldwide. Among pneumonia pathogens, it is the most common cause of hospitalisation in adults and the most frequent cause of death. Despite continuing improvements in aetiological diagnosis, effective antibiotic treatment and advances in supportive care, mortality rates in patients with pneumococcal pneumonia remain high, ranging from 5% to 35%.

Septic shock at admission is one of the most important factors influencing prognosis of patients with pneumococcal pneumonia. It is known that the intrinsic relationship between the host and the microorganism is critical in the pathogenesis of septic shock. Many host factors influence the ability to develop an optimal immune response against infection. Moreover, >90 serotypes of pneumococci have been described, defined by differences in the polysaccharide capsule, the major virulence determinant of these organisms. Improvement in the knowledge of serotypes associated with septic shock may help in the design of new vaccines. However, within serotypes, different genotypes may be identified and these genotypes are associated with the presence of different virulence determinants. The association between infecting S pneumoniae genotype and pneumonia severity has not been well established.

To date, little information is available regarding the host- and pathogen-related factors associated with pneumococcal pneumonia presenting with septic shock. We performed this prospective study to identify risk factors for septic shock and to ascertain clinical outcomes in a large and homogeneous cohort of non-severely immunosuppressed hospitalised adults with pneumococcal pneumonia. Serotypes, genotypes and antibiotic resistance of isolated strains were also analysed.

METHODS

Setting, patients and study design

The study was carried out in a 900-bed university hospital for adults in Barcelona, Spain. The hospital serves an area of 1 000 000 inhabitants and admits ~24 000 patients per year. All non-severely immunosuppressed adults admitted to the hospital with pneumococcal pneumonia through the emergency department from 13 February 1995 to 30 June 2008 were prospectively recruited and followed-up. Patients with neutropenia, HIV infection and transplantation were not included.

For the purposes of this study patients were divided into two groups: patients who presented with septic shock at admission and those who did not. (henceforth “pneumococcal pneumonia presenting with shock” and “pneumococcal pneumonia without shock”)

Clinical evaluation and follow-up

At the initial visit, before starting empirical antibiotic treatment, patients underwent a complete clinical history and physical examination. Microbiological studies included two sets of blood cultures and sputum Gram stain and culture when available. Urinary antigen detection for S pneumoniae was performed if indicated by the attending doctor. Patients were stratified into risk classes by using the validated prediction rule calculated...
Respiratory infection

according to the Pneumonia Severity Index (PSI) scores, as described elsewhere. Empirical antibiotic treatment was administered according to hospital guidelines, which recommend the administration of a β-lactam agent (ceftriaxone or amoxicillin–clavulanate) with or without a macrolide or a fluoroquinolone. Combination treatment was recommended for patients with clinical suspicion of Legionella or an atypical pathogen or in the case of severe pneumonia in the absence of a demonstrative sputum Gram stain. Levofloxacin monotherapy was allowed for selected cases (ie, patients with allergy to β-lactam agents and no prior quinolone use).

Patients were seen daily during their hospital stay by one or more of the investigators who provided medical advice when requested and recorded clinical and microbiological data in a computer-assisted protocol.

Definitions

Pneumococcal pneumonia was diagnosed in patients with signs and symptoms of an acute-onset lower respiratory tract infection, a new infiltrate on chest radiograph, one or more cultures positive for S pneumoniae obtained from blood, normally sterile fluids or sputum, and/or a positive test for detection of urinary antigen. Only good quality samples of sputum (<10 squamous epithelial cells and >25 leucocytes per field) were accepted for processing.

The diagnosis of septic shock was based on a systolic blood pressure of <90 mm Hg and peripheral hypoperfusion with the need for vaspressors for >4 h after fluid replacement at admission. Current tobacco smoking was recorded when a patient had smoked >10 cigarettes per day for at least 1 year preceding the study, and alcohol consumption when a patient had consumed >80 g of alcohol daily for at least 1 year preceding the study. Chronic corticosteroid treatment was defined as ≤20 mg/day of prednisone or its equivalent for a period of at least 30 days; patients receiving higher doses were excluded. A patient was considered to have been pneumococcal vaccinated if 23-valent polysaccharide pneumococcal vaccine had been administered in the 5 years before admission, according to the hospital and primary healthcare centre records. A patient was considered influenza vaccinated if influenza vaccine had been administered during the year prior to admission.

Early case fatality rate was defined as death due to any cause ≤48 h after hospitalisation. Overall case fatality rate was defined as death due to any cause during ≤30 days of hospitalisation.

Microbiological studies

S pneumoniae was identified using standard microbiology procedures. From 2000 onwards, urinary antigen detection using a rapid immunochromatographic assay (Now, Binax, Portland, Maine, USA) for S pneumoniae was also available. Antimicrobial susceptibility was tested by microdilution method, following the Clinical Laboratory Standard Institute methods and criteria. Serotype was identified using the Quellung reaction at the Spanish Reference Laboratory and/or by PCR following the methodology described by the Centers for Disease Control (CDC, http://www.cdc.gov/ncidod/ biotech/strep/strepindex.htm). Unusual serotype–genotype combinations were retested.

For molecular typing, all available strains were typed using pulsed-field gel electrophoresis (PFGE) after restriction with Smal. PFGE patterns were compared with those of representative international pneumococcal clones of the Pneumococcal Molecular Epidemiology Network. Sixty-six selected strains representative of main clusters (at least one strain for each PFGE pattern accounting for >2 pneumococci) were studied using multilocus sequence typing, as described elsewhere. Allele numbers and sequence types (STs) were assigned using the pneumococcal multilocus sequence typing Web site.

Statistical analysis

To detect significant differences between groups, we used the χ² or Fisher exact test for categorical variables, and the Student t test or the Mann–Whitney U test for continuous variables, when appropriate. The multivariate analysis of factors potentially associated with septic shock at admission included all the significant variables in the univariate analysis with clinical relevance. We used the stepwise logistic regression model of the SPSS software package (SPSS, version 13.5; SPSS, Chicago, Illinois, USA). Statistical significance was established at α = 0.05. All reported p values are two tailed.

RESULTS

Over the study period, 1041 consecutive adults with pneumococcal pneumonia were included, of whom 114 (10.9%) had septic shock at admission. Table 1 details the microbiological methods used to establish the diagnosis of pneumococcal pneumonia.

Clinical features of the patients according to the study group (pneumococcal pneumonia presenting with shock and pneumococcal pneumonia without shock) are shown in table 2. Patients with shock were significantly younger, were more frequently current smokers, had more frequently received chronic corticosteroid treatment and were less likely to have received prior influenza vaccine than patients without shock. They also had more frequent respiratory failure, multilobar pneumonia and impaired consciousness at admission and were more commonly classified into high-risk PSI classes than those without.

Antibiotic-resistant pneumococci with a penicillin minimum inhibitory concentration (MIC) ≥4 μg/ml (1.5% vs 1.7%; p = 1)

COPD, chronic obstructive pulmonary disease; PSI, Pneumonia Severity Index.

Moreover, the early and overall case fatality rates were higher in patients who had septic shock at admission.

Table 5 summarises the results of the multivariate analysis of factors potentially associated with septic shock. After adjustment, independent risk factors were current tobacco smoking, chronic corticosteroid treatment and infection caused by *S. pneumoniae* serotype 3. In a subanalysis of the 322 episodes of bacteraemic pneumococcal pneumonia, the only independent risk factor for septic shock was the use of chronic corticosteroid treatment (OR 6.087, 95% CI 1.908 to 19.469).

**DISCUSSION**

This prospective study offers a comprehensive evaluation of the host- and pathogen-related risk factors associated with septic shock in pneumococcal pneumonia. We found that 10.9% of patients had septic shock at admission, a figure similar to that encountered in previous studies of community-acquired pneumonia, in which the incidence of septic shock ranged from 7.4% to 10%.12 17

In our study, independent factors for septic shock were current tobacco smoking, chronic corticosteroid treatment and infection caused by *S. pneumoniae* serotype 3. Neither infecting genotype nor antibiotic resistance was found to be associated with septic shock.

Tobacco smoking has been previously associated with increased risk of infection,10–16 especially invasive pneumococcal disease.2 23–25 It has been demonstrated that smoking negatively affects the immune system, compromising the host’s ability to mount an appropriate immune and inflammatory response.23–25 To our knowledge, our study is the first to link current tobacco smoking directly with septic shock in pneumococcal pneumonia. This finding provides additional support to encourage patients at risk for pneumonia to undergo smoking cessation programmes.

Glucocorticoids exert a decisive influence on the immune function of macrophages and granulocytes, as well as in systemic cytokine expression. Additionally, chronic corticosteroid treatment suppresses the production of corticotrophin-releasing hormone and corticotrophin, and can induce adrenal atrophy.27 Consequently, the adrenal responses to infection may be insufficient to control the inflammatory situation. Although evidence from randomised trials is lacking, treatment with supplementary corticosteroids may be of benefit in patients...
with pneumococcal pneumonia and septic shock in whom there is evidence of adrenal insufficiency.

Serotype 3 is usually associated with adult pneumococcal infection and is less frequent in children and in young adults. In our study it caused nearly one in four of the cases of pneumococcal pneumonia. Interestingly, we found that serotype 3 was independently associated with septic shock. Previous studies associated serotype 3 with a low invasive potential but with higher mortality rates in bacteraemic pneumococcal pneumonia.27–33

Despite a number of strengths, our study has some limitations that should be acknowledged. First, the possible role of polymorphisms of innate immunity was not analysed. Investigating the relationship between immune system genetics and the severity of infection should therefore be a major focus of future research. Secondly, the small number of cases of pneumococcal pneumonia caused by some serotypes and genotypes precluded analysing their potential correlation with shock. Thirdly, the study was carried out in a single centre and the results might not translate to other geographic areas.

In summary, septic shock is a frequent complication of pneumococcal pneumonia and causes high morbidity and mortality. Current tobacco smoking, chronic corticosteroid treatment and infection caused by S pneumoniae serotype 3 are independent risk factors for this serious complication.
