Ca\textsuperscript{2+} homeostasis and structural and functional remodelling of airway smooth muscle in asthma

Katharina Mahn, Oluwaseun O Ojo, Gianna Chadwick, Philip I Aaronson, Jeremy P T Ward, Tak H Lee

ABSTRACT
Asthma is characterised by airway hyper-responsiveness and remodelling, and there is mounting evidence that alterations in the phenotype of airway smooth muscle (ASM) play a central role in these processes. Although the concept that dysregulation of ASM Ca\textsuperscript{2+} homeostasis may underlie at least part of these alterations has been around for many years, it is only relatively recently that the availability of ASM biopsies from subjects with mild and moderate asthma has allowed it to be properly investigated. In this article, critical components of the pathobiology of asthmatic ASM, including contractile function, proliferation, cell migration and secretion of proinflammatory cytokines and chemokines, are reviewed and related to associated changes in ASM Ca\textsuperscript{2+} homeostasis. Based on this evidence, it is proposed that a unifying mechanism for the abnormal asthmatic phenotype is dysregulation of Ca\textsuperscript{2+} homeostasis caused at least in part by a downregulation in expression and function of sarcoendoplasmic Ca\textsuperscript{2+} ATPases (SERCAs).

CONTRACTILITY OF ASM IN ASTHMA
It is widely agreed that alterations in the contractility and dynamics of ASM contribute to airway narrowing and hyper-responsiveness in asthma. The contractile apparatus of ASM is composed of myosin and actin filaments (F-actin), and regulatory protein kinases and phosphatases that control their interaction. Myosin heavy chain (MHC) has ATPase activity, and binds to two light chains including the 20 kDa regulatory light chain (MLC\textsubscript{20}). F-actin associates with regulatory proteins including tropomyosin, caldesmon and calponin, and promotes myosin assembly and ATPase activity. Contraction is normally initiated by elevation of intracellular [Ca\textsuperscript{2+}] ([Ca\textsuperscript{2+}]), Ca\textsuperscript{2+}-calmodulin-dependent activation of myosin light chain kinase (MLCK), and consequently phosphorylation of MLC\textsubscript{20} and myosin–actin cross-bridge cycling. MLC\textsubscript{20} is dephosphorylated by myosin light chain phosphatase (MLCP), which is regulated by Rho kinase, protein kinase C and telokin, so the net phosphorylation state of MLC\textsubscript{20} and therefore force production is primarily dependent on the relative activities of MLCK and MLCP\textsuperscript{9} (figure 1). However, actin-based mechanisms also play an important role through modulation of myosin ATPase activity and cytoskeletal dynamics.\textsuperscript{10} Pathways that initiate or modulate ASM contraction therefore include those that regulate [Ca\textsuperscript{2+}], Ca\textsuperscript{2+} sensitivity (via MLCP) and the actin cytoskeleton. Alterations to several such pathways have been implicated in asthma.

Increased expression of both a fast MHC isoform and MLCK has been reported in ASM from patients with asthma, which could increase the velocity of ASM shortening.\textsuperscript{2 4 11} Interestingly, Fairbank et al\textsuperscript{12} have shown that repeated increases in ASM tone lead to increased MLCK expression, MLC\textsubscript{20} phosphorylation and changes in cytoskeletal organisation, suggesting that in asthma these could be secondary phenomena. Rho kinase has also been implicated in the enhanced response of ASM from subjects with asthma,\textsuperscript{3} though it is unclear whether its expression is altered. Notably, interleukin 13 (IL-13) is reported to increase expression of RhoA, a key activator of Rho kinase, in murine ASM.\textsuperscript{13}

Cytosolic [Ca\textsuperscript{2+}] is dependent on Ca\textsuperscript{2+} entry and removal across the cell membrane, and sequestration into and release from intracellular stores including the sarcoplasmic reticulum (SR) and mitochondria.\textsuperscript{14} The highly non-linear relationship between [Ca\textsuperscript{2+}], and force in smooth muscle (due to 4:1 stoichiometry of Ca\textsuperscript{2+}–calmodulin interaction) implies that even a small subthreshold increase in [Ca\textsuperscript{2+}], could greatly increase subsequent responses to agonists. It was therefore suggested decades ago that the exaggerated contractile response of ASM typical of asthma could result from abnormal Ca\textsuperscript{2+} handling.\textsuperscript{15} This also has implications for mechanisms other than contraction.

PROLIFERATION AND MIGRATION OF ASM IN ASTHMA
ASM hyperplasia and proliferation may account for the increased ASM mass characteristic of asthma,\textsuperscript{5} and have been associated with increased ASM cell movement.
division, an altered ECM and reduced apoptosis. Cytokines, growth factors and ECM proteins induce ASM hyperplasia, and platelet-derived growth factor (PDGF), epidermal growth factor (EGF), T helper 2 (Th2) cytokines (IL-13 and IL-4), leukotriene D₄ (LTD₄) and transforming growth factor (TGFB) all increase proliferation of ASM in vitro. All these mitogens appear to activate the GPase p21Ras, which in turn activates phosphatidylinositol 3-kinase (PI3 kinase) or extracellular signal-regulated kinase (ERK); both of these regulate ASM proliferation mediated via cyclin D1 promoter. Glucocorticoids, a mainstay of asthma treatment, suppress proliferation in part via decreasing cyclin D1 expression, mediated by a complex of the glucocorticoid receptor and C/EBP/ enhancer-binding protein C (C/EBPz). However, ASM from subjects with asthma exhibits a tissue-specific lack of C/EBPz, and this has been postulated to confer an ASM phenotype that is more susceptible to mitogenic and contractile stimuli.

Migration of proliferating ASM and precursor cells may contribute to increased ASM mass in asthma, and involves reorganisation of the actin cytoskeleton, assembly of focal contacts and myosin—actin-mediated force generation. Many factors integrate to promote actin disassembly, polymerisation and attachment to focal adhesions, and regulation of myosin activity; several are also involved in ASM growth (eg, PI3 kinase and ERK) and contraction (eg, MLCK, MLCP, RhoA and Rho kinase) (see review by Gerthoffer). While the role of cell migration in airway remodelling remains unclear, ASM cells derived from subjects with asthma exhibit enhanced migration. Migration is strongly Ca²⁺ dependent, as myosin activity is regulated by Ca²⁺—calmodulin-dependent activation of MLCK, and reorganisation of the actin cytoskeleton involves several Ca²⁺-dependent mechanisms, notably the actin-severing protein gelsolin.

SECRETION OF CYTOKINES AND CHEMOKINES IN ASTHMA
ASM is a rich source of chemokines and cytokines, including eotaxin, RANTES (regulated upon activation, normal T cell expressed and secreted), TARC (thymus and activation-regulated chemokine), SCF (stem cell factor) and GM-CSF (granulocyte–macrophage colony-stimulating factor). For example, eotaxin release following stimulation of ASM with IL-13 or IL-4 mediates eosinophil recruitment, and ASM-derived RANTES induces chemotaxis of inflammatory cells, thereby contributing to the inflammatory process. Ca²⁺ signalling has an important role in release of cytokines and chemokines (eg, Denecker et al), and the finding that IL-13-induced eotaxin-1 secretion from healthy ASM is enhanced by knockdown of SERCA2 also implicates a key role for [Ca²⁺].

CA²⁺ HOMEOUSTASIS IN ASM
Intracellular Ca²⁺ has a central role in transduction of signals leading to diverse cellular responses, including contraction, metabolism, cell motility and protein secretion, as well as cell differentiation and proliferation. As such, it has long been suggested that alterations in ASM Ca²⁺ homeostasis may be central to the development of the asthmatic ASM phenotype and hyper-responsiveness. Elevation of ASM [Ca²⁺] can be elicited by activation of Ca²⁺ influx pathways and/or release from the SR. Ca²⁺ then binds to and stimulates high affinity binding proteins such as calmodulin, which activates MLCK, and the phosphatase calcineurin, which activates the transcription factor NFAT (nuclear factor of activated T cells) and indirectly NF-kB (nuclear factor-kB), both of which are implicated in inflammation and airway remodelling in asthma. ASM [Ca²⁺] is pumped back into the SR or out of the cell in order to terminate its effects, the former mediated by the SERCA, and the latter by the plasma membrane Ca²⁺ ATPase (PMCA) and Na²⁺/Ca²⁺ exchanger (NCX) (figure 2).

Agonists binding to Go/G₁₁ protein- or tyrosine kinase-coupled receptors can initiate elevation [Ca²⁺], via phospholipase C (PLC)-mediated generation of diacylglycerol (DAG) and inositol trisphosphate (IP₃). DAG activates non-selective cation channels (permeable to both Na²⁺ and Ca²⁺), often referred to as receptor-operated channels (ROC₆) and TRPC6 (transient receptor potential channel 6) proteins which are expressed in human ASM. IP₃ binds to IP₃ receptors (IP₃R), causing a rise in cytosolic Ca²⁺. Ca²⁺ then binds to and activates myosin light chain kinase (MLCK) via Ca²⁺—calmodulin (CaM).

Highlighted boxes mark changes reported in asthma or following stimulation with interleukin 13 (IL-13). See text for details.
Figure 2  Ca\(^{2+}\) mobilisation pathways in airway smooth muscle (ASM).

Binding of an agonist to a G-protein-coupled receptor activates phospholipase C (PLC) to generate diacylglycerol (DAG) and inositol trisphosphate (IP\(_3\)). DAG activates receptor-operated channels (ROCs), eliciting Na\(^{+}\) and Ca\(^{2+}\) entry, while IP\(_3\) activates clusters of IP\(_3\) receptors (IP\(_3\)Rs) on the sarcoplasmic reticulum (SR), causing Ca\(^{2+}\) release which may activate adjacent ryanodine receptors (RyRs) to increase the frequency of sparks. RyRs may also be activated or potentiated by cADP ribose (cADPR).

Store depletion is sensed by stromal-interacting molecule 1 (STIM1) within the SR, which translocates to and activates store-operated channels (SOCs). The elevation in subplasmalemmal [Na\(^{+}\)] resulting from reverse-mode operation of Na\(^{+}/\)Ca\(^{2+}\) exchanger (NCX), leading to Ca\(^{2+}\) entry. Much of the Ca\(^{2+}\) entering the cell and released from stores may be sequestered by the superficial SR through sarcoendoplasmic Ca\(^{2+}\) ATPases (SERCAs) and mitochondria. Cycling between SR Ca\(^{2+}\) uptake and release mechanisms leads to Ca\(^{2+}\) oscillations. Ca\(^{2+}\) is removed from the cell by the plasma membrane Ca\(^{2+}\) ATPase (PMCA) and normal operation of the NCX. TRPC, transient receptor potential channels.

(IP\(_3\)Rs) in the SR to initiate Ca\(^{2+}\) release and highly localised elevations in [Ca\(^{2+}\)] (‘puffs’), which consequently activate ryanodine receptors (RyRs) in the SR (Ca\(^{2+}\)-induced Ca\(^{2+}\) release, CICR), thereby amplifying the elevation in cytosolic [Ca\(^{2+}\)] and leading to Ca\(^{2+}\) ‘sparks’, and potentially regenerative Ca\(^{2+}\) waves and oscillations.45 RyRs are also activated by cADP ribose (cADPR), which is synthesised by the multifunctional enzyme CD38 (an ADP-ribose cyclase) and may contribute to generation of Ca\(^{2+}\) sparks and waves; it has been proposed that this pathway plays an important role in ASM.46 It has been reported that some agonists such as LTD4 do not elicit IP\(_3\)-mediated Ca\(^{2+}\) release in human bronchioles, but do activate Ca\(^{2+}\) entry via ROCs.42

Depletion of SR Ca\(^{2+}\) content by the above processes activates store-operated Ca\(^{2+}\) entry (SOCE) via the SR Ca\(^{2+}\)-sensing protein stromal-interacting molecule 1 (STIM1), which associates with the plasmalemmal protein Orai causing it to form channels which mediate SOCE.47 48 In smooth muscle many studies suggest that the channels underlying SOCE (store-operated channels; SOCs) are non-selective (ie, Na\(^{+}\) and Ca\(^{2+}\) permeable), unlike classical STIM1–Orai which is Ca\(^{2+}\) selective. Possibly explaining this, there is evidence that the STIM1–Orai complex also incorporates TRPC proteins in smooth muscle, although this remains controversial.49 50 As the degree of SR Ca\(^{2+}\) loading regulates SOCE, SERCA activity directly influences Ca\(^{2+}\) influx.

Removal of Ca\(^{2+}\) from the smooth muscle cell is handled by PMCA and NCX. PMCA is an ATP-dependent transporter activated by protein kinase G and A,44 providing one mechanism by which agents such as β\(_2\)-adrenoceptor agonists cause ASM relaxation. NCX uses the Na\(^{+}\) electrochemical gradient to pump out 1 Ca\(^{2+}\) in exchange for 3 Na\(^{+}\), and as such is dependent on membrane potential and cytosolic [Na\(^{+}\)]. Elevation of subcellular [Na\(^{+}\)] can therefore cause reverse-mode operation of NCX and Ca\(^{2+}\) entry, and there is evidence that in ASM agonist-induced Na\(^{+}\) entry through non-selective cation channels (see above) does just this, with NCX then contributing to the elevation of [Ca\(^{2+}\)], and store refilling.50 51

The intracellular structure of ASM is highly organised, with peripheral SR, mitochondria and plasmalemma closely approximated in localised signalling microdomains. This provides a ‘superficial buffer barrier’, which buffers Ca\(^{2+}\) entry and limits its pervasion into the deeper cytosol, and through its highly regulated Ca\(^{2+}\) release and uptake mechanisms provides a level of precise control over the spatial and temporal characteristics of changes in [Ca\(^{2+}\)].52 53 54 As such, it facilitates a high level of cross-talk between these organelles and consequently the mechanisms discussed above, and thus the ability to engender regenerating Ca\(^{2+}\) waves and oscillations. In ASM, agonists have indeed been shown to evoke Ca\(^{2+}\) waves or sustained oscillations of [Ca\(^{2+}\)], caused by sequential Ca\(^{2+}\) release from and re-uptake into the SR, involving IP\(_3\)Rs, RyRs and SERCAs55 56 57 (figure 2). These waves seem to be responsible for acetylcholine-mediated contraction in human ASM, since their suppression by blockade of SERCAs or RyRs causes relaxation.58 Ca\(^{2+}\) entry is nevertheless important, as wave activity is terminated and contraction strongly suppressed by blockade of non-selective cation channels (ie, SOCs and ROCs) and reverse-mode NCX, although inhibition of L-type Ca\(^{2+}\) channels has only a minor effect.59 60 This implies that Ca\(^{2+}\) entry is primarily voltage independent and funnelled into the SR rather than serving to elevate [Ca\(^{2+}\)], directly. Importantly, Ca\(^{2+}\) waves and oscillations also activate other Ca\(^{2+}\)-dependent processes, including gene transcription.59 60

SERCAs clearly play a critical role in the above processes. There are three tissue-specific members of the mammalian SERCA family, SERCA1, SERCA2 and SERCA3, of which SERCA2 is expressed in muscle cells. Alternative splicing of exon 20 of the ATP2A2 gene gives rise to SERCA2A, SERCA2B and SERCA2C mRNA transcripts, which differ in the final exon
usage. We have recently demonstrated that the predominant isoform in ASM is SERCA2B, with the other splice variants expressed at very low levels. SERCAs are regulated by phospholamban, which under basal conditions acts to inhibit their activity. When phospholamban is phosphorylated, for example by protein kinase A, this inhibition is relieved and SR Ca\(^{2+}\) uptake dramatically increased. This provides another important mechanism by which cAMP-raising agents induce bronchial relaxation.

**ALTERED ASM CA\(^{2+}\) HOMEOSTASIS IN ASTHMA: ROLE OF SERCAs**

We have recently reported that SERCA2 protein expression in both native and cultured ASM from endobronchial biopsies of patients with mild and moderate/severe asthma is diminished compared with that of healthy subjects; the extent of this effect correlated with disease severity. Agonist-induced Ca\(^{2+}\) release from the SR was similarly depressed, consistent with a reduced store content, and the rate at which bradykinin-induced elevation of [Ca\(^{2+}\)]\(_i\) recovered to baseline levels was significantly slowed (figure 3). In addition, ASM cells from subjects with asthma were significantly more active in a Ca\(^{2+}\)-dependent spreading assay that reflects migration. Importantly, suppression of SERCA2 by small interfering RNA (siRNA) in ASM cells derived from donors without asthma recapitulated the effect of SERCA2 knockdown. Interestingly, IL-13- and TNF\(\alpha\)-induced hyper-responsiveness has also been associated with decreased expression of the BMPR-II receptor caused by familial pulmonary arterial hypertension, which is associated with the decreased expression of the BMPR-II receptor caused by autosomal dominant mutations in the BMPR2 gene.

It is not yet known whether the decrease in ASM SERCA2 expression in asthma could have a genetic basis, in which case it might be expected that downregulation of SERCA2 would be observed in other types of cell. Although asthma has not been associated with cardiac dysfunction, which might be predicted if SERCA2 expression is also reduced in cardiac myocytes, patients with Darier disease also do not exhibit any abnormalities of cardiac function. Thus even this substantial genetically determined deficit in SERCA2 can cause abnormalities which manifest only in certain types of cell. It may therefore be that mutations in the ATP2A2 gene, or in genes which affect its expression, exist in those with asthma, but for some reason exert restricted effects. This would be analogous to the situation in familial pulmonary arterial hypertension, which is associated with a decreased expression of the BMPR-2 receptor caused by autosomal dominant mutations in the BMPR2 gene. However, this mutation has a penetrance of only \(~\sim\)20% and, even though cAMP function is important in other organs, causes a lung-specific pathology. This implies that the disease only manifests itself when other factors are present (‘second hit’ hypothesis). It is, for example, feasible that a localised functional suppression of SERCA2 activity may also occur in the powerfully oxidising and cytokine-rich milieu of the inflamed asthmatic lung which could constitute a focal ‘second hit’ sufficient to cause a significant effect on cellular Ca\(^{2+}\) handling restricted mainly to these cells. Interestingly, it has recently been reported that SERCA function is inhibited by ORMDL3, which is implicated in the inflammation-promoting unfolded protein response and has been identified as a genetic risk factor for childhood asthma. This is of clear relevance to whether the observed reduction in ASM SERCA2 expression is of genetic origin or secondary to an increase in proinflammatory cytokines. It is noteworthy that the disease severity-related fall in SERCA2B expression persisted in ASM cells through multiple

**Figure 3** Recovery of Ca\(^{2+}\) transient is delayed in airway smooth muscle (ASM) cells from subjects with asthma. passages in culture, suggesting either a genetic or an epigenetic origin. Downregulation of SERCA2 function has previously been reported to promote proliferation in a number of tissues including other smooth muscles, possibly mediated via calcineurin. It is noteworthy in this regard that ciclosporin, a calcineurin antagonist, has been used as a treatment for steroid-resistant asthma. Trian et al have proposed that the enhanced proliferation in ASM from subjects with asthma is due to an increase in mitochondrial mass, driven by upregulation of mitochondrial transcription factors as a consequence of altered ASM Ca2+ homeostasis. While it is unclear how increased mitochondria might promote proliferation, this mechanism could be an important downstream effector pathway for SERCA dysfunction, although Trian et al advocated an enhanced Ca2+ entry pathway. Notably, a variety of Ca2+ influx pathways are also upregulated when SERCA expression or function is suppressed, for example NCX and TRPC proteins in cardiomyocytes, again associated with an increase in transcript levels of a calcineurin-dependent transcription factor complex and activity of NFAT. It is therefore interesting that ASM proliferation has been associated with a marked upregulation of TRPCs.

As SERCA2 plays a key role in the operation of the superficial buffer barrier and generation of Ca2+ oscillations, it can be predicted that reduced expression and/or function of SERCA2 would result in not only increased basal levels of [Ca2+], but also potentiation of Ca2+ influx-induced elevations of [Ca2+]i and altered dynamics of Ca2+ oscillations. Consistent with this, an increased resting [Ca2+]i and slowing of Ca2+ oscillations has been observed in ASM under conditions where SERCA activity is reduced. This could underpin, at least in part, ASM hyper-responsiveness to agonists and, through alterations to the frequency of Ca2+ oscillations, differential activation of transcription factors such as NFAT and NF-kB.

CONCLUSION

It is clear that Ca2+ signalling plays a central and critical role in most if not all of the cellular processes that are known to be altered in ASM from subjects with asthma, including contractility, responsiveness to agonists, proliferation, migration and secretion of inflammatory mediators. We therefore propose that a unifying mechanism for the abnormal asthmatic phenotype is dysregulation of Ca2+ homeostasis, mediated at least in part by downregulation of SERCA2 expression and function driven by proinflammatory mediators. Many questions remain unanswered, including whether the reduction in SERCA2 expression is induced or of genetic origin, and whether observed changes in other Ca2+ homeostatic mechanisms occur independently or are secondary to reduced SERCA2 function. However, the fact that experimental suppression of SERCA2 expression in healthy ASM appears to recapitulate key aspects of the asthmatic phenotype strongly suggests that SERCA2 downregulation plays a central role in the altered function of asthmatic ASM.
