A 41-year-old with idiopathic myelofibrosis was referred to the chest clinic with a 1-month history of progressive dyspnoea and intermittent wheeze. There was no history of haemoptysis and the patient was a lifelong non-smoker. On examination, the patient was afebrile, cachectic and had hepatosplenomegaly. Haemoglobin was 6.0 g/dl, white cell count 3.6×10^9/l, platelet count 98×10^9/l. Blood smear showed marked anisopoikilocytes, prominent tear drop cells and polychromasia. Bone marrow aspirate was hypercellular, showed reduction in the degree of maturation, and a marked decrease in the proportion of erythroid cells. There was no evidence of acute leukaemia or metastatic malignancy. Microbiologic analysis of the sputum and blood for pulmonary infection was negative. Lung function test showed a restrictive pattern and a DLco of 32% predicted. Chest radiography demonstrated diffuse bilateral reticular interstitial infiltrates and bibasal septal lines. A subsequent CT of the chest demonstrated diffuse bilateral smooth and nodular interlobular septal thickening with centrilobular nodules (figure 1). There was no echocardiographic or radiological evidence of pulmonary hypertension.

On the basis of the patient’s unexplained progressive dyspnoea, impaired gas transfer and CT findings, an open VATS-assisted lung biopsy was performed. Histology demonstrated pulmonary congestion and haemorrhage (figure 2) and numerous dark-staining hyperchromatic cells with multinucleated nuclei within alveolar capillaries. On CD42B immunostain and high power (inset figure 3), these cells were confirmed as megakaryocytes (figures 2 and 3). The absence of CD34 expression (inset figure 2) in the peribronchiolar immature myeloid precursor cells and lymphoid cells excluded leukaemic infiltration. There was no evidence of interstitial fibrosis. The histology was consistent with pulmonary extramedullary haemopoiesis (EMH). The patient was started on cytoreductive hydroxy-carbamide and referred to the local bone marrow transplant unit.

EMH is the development and growth of haematopoietic tissue outside of the bone marrow. Although essential in foetal life, its occurrence after birth is abnormal. As in physiologic foetal EMH, the liver, spleen and lymph nodes are the most common sites of pathologic EMH,1 however...
Chest clinic

thoracic EMH has been described. Pleural-based tumours and paraspinal masses are the most common thoracic manifestations of EMH, while pulmonary interstitial EMH is rare and usually occurs in patients with an antecedent haematologic disorder. In suspected pulmonary EMH, surgical lung biopsy is required to allow immunohistochemical staining for erythroid, myeloid and megakaryocyte precursors, which typically follow the pulmonary lymphatics. The CT findings of pulmonary EMH are non-specific. However, when this pattern of interlobular septal thickening and centrilobular nodules is encountered in a patient with a haematological malignancy, the diagnosis of pulmonary interstitial EMH should be considered.
