ABSTRACT

Rationale Hospitalised patients with acute exacerbation of COPD may deteriorate despite treatment, with early readmission being common.

Objectives To investigate whether neural respiratory drive, measured using second intercostal space parasternal muscle electromyography (EMGpara), would identify worsening dyspnoea and physician-defined inpatient clinical deterioration, and predict early readmission.

Methods Patients admitted to a single-site university hospital with exacerbation of COPD were enrolled.

Spirometry, inspiratory capacity (IC), EMGpara routine physiological parameters, modified early warning score (MEWS), modified Borg scale for dyspnoea and physician-defined episodes of deterioration were recorded daily until discharge. Readmissions at 14 and 28 days post discharge were recorded.

Measurements and main results 120 patients were recruited (age 70±9 years, forced expiratory volume in 1 s (FEV1) of 30.5±11.2%). Worsening dyspnoea, defined as at least one-point increase in Borg scale, was associated with increases in EMGpara%max and MEWS, whereas an increase in EMGpara%max alone was associated with physician-defined inpatient clinical deterioration. Admission-to-discharge change (Δ) in the normalised value of EMGpara (%ΔEMGpara%max) was inversely correlated with ΔFEV1 (r=−0.38, p<0.001) and ΔIC (r=−0.44, p<0.001).

ΔEMGpara%max predicted 14-day readmission (OR 1.13, 95% CI 1.03 to 1.23) in the whole cohort and 28-day readmission in patients under 85 years (OR 1.09, 95% CI 1.03 to 1.18), also predicted 28-day readmission in the whole cohort.

Conclusions Measurement of neural respiratory drive by EMGpara represents a novel physiological biomarker that may be helpful in detecting inpatient clinical deterioration and identifying the risk of early readmission among patients with exacerbations of COPD.

Trial registration NCT01361451.

INTRODUCTION

Acute exacerbations of COPD (AECOPD) are common, accounting for 12.5% of emergency admissions in the UK1 with an in-hospital mortality of up to 10%.2 Eighteen percent of patients with AECOPD present to the emergency department with acute hypercapnic respiratory failure3 and a further 5% will develop late respiratory acidosis.

Twenty percent of hospitalised patients with AECOPD are readmitted within 28 days,4 5 and financial penalties are now in operation for acute care hospitals in the UK and USA for readmissions within 30 days.6 7 It is a health economic priority to identify COPD treatment failure promptly and reduce readmissions, and biomarkers that can achieve this will therefore be of significant clinical value.

Previous studies have reported the patient characteristics that predict readmission among hospitalised patients with COPD,2 8–11 but these are limited by their dependence on non-modifiable parameters, rather than on the trajectory of response to treatment. In addition, early-warning scores,12 often used to track inpatient clinical deterioration and trigger escalation of care, vary in their ability to predict outcomes such as critical care admission and hospital mortality,13 limiting the usefulness of these approaches.

More advanced physiological measurements of elastic and threshold respiratory load are difficult...
during an acute exacerbation as invasive monitoring of pleural pressure is poorly tolerated. In addition, the measurement of ventilation in flow-limited patients characterised by neuroventilatory uncoupling, as a result of severe hyperinflation, has significant caveats and therefore the non-invasive measurement of neural respiratory drive (NRD), which is a direct reflection of the imbalance between respiratory muscle load and capacity, would be a preferred option. Indeed, NRD as an advanced physiological biomarker, provides a direct measure of the balance between respiratory muscle load and capacity, and has gained increasing attention in the acute setting.

Recently, surface electromyography (EMG) of the second intercostal space parasternal muscles (EMG\textsubscript{\text{para}}) has been used as a non-invasive alternative to the invasive oesophageal measurement\textsuperscript{15} of NRD in patients with COPD, asthma and cystic fibrosis.\textsuperscript{15 17 18} Murphy et al\textsuperscript{15} previously showed, in a pilot feasibility study of this technique, that the change in NRD during hospital admission was a biomarker of physician-defined clinical deterioration, and furthermore, change in NRD from admission to discharge identified patients with COPD who were readmitted within 14 days. However, this previous study was in a small group of selected patients with COPD, with the majority of patients having only a single pair of NRD measurements made during their hospital admission.

We therefore hypothesised that, in a large, prospective observational cohort study of patients hospitalised with exacerbation of COPD, changes in daily measurements of NRD between hospital admission and discharge would predict readmission within 14 and 28 days. We further hypothesised that change in NRD during hospital admission would objectively identify worsening dyspnoea and physician-defined clinical deterioration.

**METHODS**

**Patients**

The study was approved by the London-Bentham Research Ethics Committee and participants provided written informed consent. The authors registered the study as an observational cohort study (NCT01361451). Patients with a physician diagnosis of acute exacerbation of COPD, defined according to clinical features and basic investigations,\textsuperscript{1} were enrolled within 12 h of admission to a UK teaching hospital. The requirement for admission was determined by the attending physician. Patients were excluded if they had another cause for their acute admission (eg, acute heart failure, PE), cognitive impairment, active cancer or significant psychosocial factors.

**Admission data**

Demographic and anthropometric data were collected. FEV\textsubscript{1}, FVC and inspiratory capacity (IC)\textsuperscript{19} were measured using a pneumotachometer (3830, Hans-Rudolph, Shawnee, USA) or a handheld spirometer (Micro, Carefusion, Basingstoke, UK) according to international standards.\textsuperscript{20} Symptoms were assessed using the Medical Research Council (MRC) Dyspnoea scale,\textsuperscript{21} the modified Borg scale for dyspnoe\textsuperscript{22} and the COPD Assessment Test (CAT).\textsuperscript{23} Standard physiological observations (respiratory rate, heart rate, oxygen saturation, body temperature and blood pressure) were collected; an aggregate score derived from these was recorded as the modified early warning score (MEWS), according to local protocol.

**EMG\textsubscript{para} measurement**

EMG\textsubscript{para} was measured with patients in a semi-recumbent or seated position, as previously described.\textsuperscript{15} After skin preparation, two surface electrodes (Blue Sensor Q, Ambu, St Ives, UK) were placed in the second intercostal spaces, immediately lateral to the sternum. The skin was marked to allow placement of electrodes in an identical position throughout the study. Nasal cannulae connected to a differential pressure transducer (Technical services, Lane Fox Respiratory Unit, London, UK) identified inspiration and expiration phases (figure 1). EMG\textsubscript{para} signals were amplified and sampled at 2 kHz (Dual Bioamp and Powerlab, AD Instruments, Chalgrove, UK). Signals were analysed using Labchart software (AD Instruments) on a personal computer. The peak root mean square EMG\textsubscript{para} activity for each inspiration was averaged over 1 min of tidal breathing and normalised to a value of EMG\textsubscript{para} obtained during a maximal inspiratory sniff manoeuvre, obtained before each measurement.\textsuperscript{15} Two measures of NRD were derived, including (1) EMG\textsubscript{para/rms}\textsubscript{\text{max}} the mean peak inspiratory tidal EMG\textsubscript{para} normalised to the maximal manoeuvre; and (2) NRDI (Neural Respiratory Drive Index), the product of EMG\textsubscript{para/rms}\textsubscript{\text{max}} and respiratory rate.\textsuperscript{15}

**Study protocol**

EMG\textsubscript{para} modified Borg scale, FEV\textsubscript{1}, FVC and IC were measured at least daily, between admission and medical fitness for

**Figure 1** Representative trace of nasal pressure and second intercostal space parasternal electromyogram during tidal breathing in a patient with COPD during an exacerbation. $P_{np}$, nasal pressure; $EMG_{para}$, parasternal electromyogram; $RMS_{para}$, root mean square of $EMG_{para}$.
discharge, and at least 2 h after the last bronchodilator dose. Medical fitness for discharge was determined by the senior attending physician, which was either senior resident or consultant. Supplemental oxygen was provided as instructed by the attending physicians. Patients were settled at rest for 7 min before EMG_{para} traces were acquired for analysis. Patients requiring non-invasive ventilation (NIV) had measurements taken after 10 min off NIV. The attending physicians, who were blinded to EMG_{para} data, were asked to provide an opinion regarding clinical improvement or deterioration between successive assessments. EMG_{para} data were analysed after patients’ discharge from hospital. Data for readmissions and deaths were obtained from patients and their relatives, and from medical records. Admission-to-discharge changes in EMG_{para}\%\text{max} and NRDI were expressed as ΔEMG_{para}\%\text{max} and ΔNRDI, respectively. Changes in EMG_{para}\%\text{max} and NRDI between consecutive inpatient measurements were denoted ΔEMG_{para}\%\text{max,cons} and ΔNRDI_{cons}, respectively.

### Primary endpoint and power calculation

Although this was an observational cohort study, an a priori primary endpoint of 28-day readmission was taken as this was considered to have major clinical relevance to the current financial penalty systems for readmission in the UK and USA. Secondary endpoints were 14-day readmission and clinical deterioration, defined by (1) at least one-point increase in Borg scale between consecutive recordings, or (2) attending physician opinion. A sample size of 120 was determined from published pilot data with a presumed 28-day readmission rate of 20% to detect a difference in NRDI of 203/min between readmitted and non-readmitted patients with a power of 80%.

### Statistical analysis

Paired data were analysed using t or Wilcoxon signed-rank tests. Readmitted and non-readmitted groups were compared using independent t or Mann–Whitney U tests. Death after discharge without early readmission was analysed together with readmissions. Logistic regression and receiver-operator characteristic (ROC) analyses were used to identify, and test the utility of, predictors of readmission. Kaplan–Meier plots and Wilcoxon signed-rank tests. Readmitted and non-readmitted groups were compared using t or Wilcoxon signed-rank tests.

### RESULTS

#### Admission, clinical course and readmission data

A total of 131 patients were enrolled between January 2011 and September 2013 (see online supplementary figure E1), and 120 patients completed the study between admission and discharge (table 1). Twenty (16.7%) patients were unable to perform FEV₁ and FVC manoeuvres at admission, while 27 (22.5%) patients could not perform admission IC manoeuvres. Three (2.5%) patients declined arterial blood gas sampling. Eight (6.7%) patients required NIV or high-dependency care following admission to hospital. There were no patients who received high-flow humidified oxygen therapy. A further three (2.5%) patients deteriorated more than 12 h after admission and required NIV. Median length of hospital stay was 3 (IQR 2–6) days. Median interval from the date of medical fitness for discharge to the date of discharge was 0 (IQR 0–1) days. One patient died 3 days after discharge from hospital.

Fourteen-day and 28-day readmission rates were 12.5% and 21.7%, respectively. The single death was analysed with the readmission data.

### Early warning scores, symptom scores and physiological data

MEWS, modified Borg scale and CAT scores all improved from admission to discharge (table 2). FEV₁, FVC and IC increased over this period, with a concomitant fall in EMG_{para}\%\text{max} and NRDI (table 2).

**Relationship between NRD, physiological parameters and dyspnoea**

Admission-to-discharge change (Δ) in EMGpara%max was inversely correlated with ΔFEV\(_1\) (r=-0.38, p<0.001), ΔFVC (r=-0.31, p=0.003) and ΔIC (r=-0.44, p<0.001) (figure 2). However, there was no correlation between ΔEMGpara%max and ΔModified Borg scale, ΔCAT score or ΔMEWS. Increases in FEV\(_1\) and IC were independently associated with reductions in EMGpara%max on multiple linear regression analysis (ΔFEV\(_1\) standardised coefficient β=-0.36, p=0.001; ΔIC β=-0.26, p=0.019). ΔEMGpara%max was weakly correlated with age (r=+0.24, p=0.009). ΔNRDI was weakly inversely correlated with ΔFEV\(_1\) (r=-0.30, p=0.004), ΔFVC (r=-0.29, p=0.007) and ΔIC (r=-0.40, p<0.001), as well as with body mass index (r=-0.27, p=0.003). There were no correlations between ΔNRDI and ΔBorg scale or ΔMEWS.

**Predictors of readmission within 28 days**

Twenty-seven (22.5%) patients were readmitted or died within 28 days of hospital discharge. Independent sample analysis showed significant differences in age, MRC grade, admission haemoglobin levels, hospital admission frequency in the previous 12 months (admission frequency), ΔEMGpara%max and ΔNRDI between readmitted and non-readmitted groups at 28 days (table 3). There were no significant differences in the values of EMGpara%max and NRDI at discharge between the two groups. With the exception of the MRC grade, univariate analysis demonstrated that all of these parameters predicted readmission at 28 days (table 4). However, in multivariable stepwise logistic regression analysis, only age and admission frequency predicted 28-day readmission (adjusted OR 1.08, 95% CI 1.03 to 1.14, p=0.004, and adjusted OR 1.29, 95% CI 1.01 to 1.66; p=0.043, respectively). Change in EMGpara%max between admission and discharge did not predict 28-day readmission in the whole cohort. The rate of radiographic consolidation was not significantly different between the two groups (11.1% for the readmitted vs 23.7% for the non-readmitted group; p=0.16).

In accordance with the correlation, albeit weak, between ΔEMGpara%max and age, a post hoc, exploratory analysis was performed among patients below an arbitrary age cut-off of 85 years (n=112). There were 23 (20.5%) readmissions within 28 days among these patients. Under these circumstances, older age (adjusted OR 1.10, 95% CI 1.02 to 1.16; p=0.017) and increasing EMGpara%max between admission and discharge (adjusted OR 1.09, 95% CI 1.01 to 1.18, p=0.023) were predictive of 28-day readmission. ROC analysis for the prediction of 28-day readmission in patients under 85 years produced an area under the ROC curve (AUC) of 0.70 for age and 0.66 for ΔEMGpara%max.

**Predictors of readmission within 14 days**

Sixteen (13.3%) patients were readmitted or died within 14 days of discharge. There were differences in MRC grade and...
ΔEMGpara%max between the readmitted and non-readmitted groups (table 5), but MRC grade did not predict 14-day readmission in the univariate logistic regression model (table 6).

Only admission-to-discharge increases in EMGpara%max (adjusted OR 1.12, 95% CI 1.03 to 1.21, p = 0.005) predicted 14-day readmission on multivariable stepwise logistic regression analysis. ROC analysis for the prediction of 14-day readmission gave an AUC of 0.70 for ΔEMGpara%max. By contrast, AUC for ΔFEV1 and ΔRC were 0.57 and 0.56, respectively (figure 3). The failure of ΔEMGpara%max to fall by more than 3.1% between admission and discharge had a sensitivity of 93.8% and a specificity of 41.3% to detect 14-day readmission, with a positive predictive value (PPV) of 19.7% and a negative predictive value (NPV) of 97.7%. Again, there was a non-significant difference in the rate of radiographic consolidation between the groups (6.25% for the readmitted vs 23.1% for the non-readmitted group, p = 0.123).

When ΔNRDI was used instead of ΔEMGpara%max in the regression model as a measure of NRD, it also predicted 14-day readmission or death (ΔNRDI: OR 1.003, 95% CI 1.001 to 1.006, p = 0.011). ROC analysis for the prediction of 14-day readmission gave an AUC of 0.70 for NRDI.

Detection of in-hospital clinical deterioration

A total of 475 pairs of consecutive EMGpara data were acquired from the 122 patients who provided at least one pair of analysable data; although 120 patients completed investigations between hospital admission and discharge, two further patients gave at least one pair of analysable data before withdrawal from the study. Patients had a median of three pairs of measurements (range 1–23) between admission and discharge. There were 116 episodes of worsening dyspnoea, defined as at least one-point increase in Borg scale. On univariate GLMM analysis, an increase in MEWS (ΔMEWScons) and in EMGpara%max (ΔEMGpara%max,cons) between consecutive recordings was associated with symptomatic deterioration (table 7). Multivariable GLMM analysis showed that ΔMEWScons (adjusted OR 1.36, 95% CI 1.01 to 1.84, p = 0.04) and ΔEMGpara%max,cons (adjusted OR 1.07, 95% CI 1.01 to 1.14, p = 0.027) were independently associated with worsening of dyspnoea. Multivariable GLMM analysis showed that ΔNRDI,cons (coefficient 0.05, 95% CI 0.01 to 0.09, p = 0.024) and ΔRC cons (coefficient −1.11, 95% CI −2.19 to −0.03, p = 0.044) were independently associated with changes in Borg scale of any magnitude between consecutive recordings.

There were 35 episodes of physician-defined deterioration. Only an increase in EMGpara%max between consecutive measurements was associated with physician-defined deterioration (ΔEMGpara%max,cons OR 1.030, 95% CI 1.003 to 1.055, p = 0.03).

CAT, COPD Assessment Test; EMGpara%max, 1 min mean magnitude of rectified inspiratory parasternal EMG activity normalised to a maximal manoeuvre; MRC, Medical Research Council; NRDI, Neural Respiratory Drive index.
In this single-centre validation study of an advanced physiological biomarker performed in an unselected cohort of acutely unwell patients with COPD, the failure of NRD to fall between admission and discharge predicted readmission within 14 days of discharge. Furthermore, this failure was predictive of readmission within 28 days in those patients under 85 years of age, but not in the cohort as a whole. In addition to the utility of this test to predict clinical outcome following hospital discharge, an increase in NRD between consecutive daily measurements detected episodes of worsening dyspnoea and physician-defined in-hospital clinical deterioration. The physiological rationale of employing NRD was strongly supported by the relationship with change in respiratory muscle physiological load between admission and discharge.

Critique of the method

Every attempt was made to enrol consecutive eligible patients with a screening to recruitment ratio of 3.4:1 achieved, which is acceptable for such an observational detailed physiological study. Few of the patients enrolled into this study required non-invasive or invasive ventilation at admission, which adds to the generalisability of this study and indeed the current cohort was wholly representative of UK patients admitted to the acute medical wards. Patients presenting in acute hypercapnic respiratory failure were frequently unable to provide written informed consent, and the study did not have ethical approval for proxy assent and retrospective patient consent.

In line with our previous work, up to one-fifth of patients were unable to perform forced respiratory manoeuvres at admission, which supports the clinical rationale for non-invasive measurements, such as EMGpara, being performed during resting tidal breathing. This could be accommodated into the routine monitoring of acutely unwell patients with COPD as a measure of the respiratory load–capacity balance. The acquisition of respiratory EMG needs to be performed in a standardised manner as variations in electrode position and skin preparation can have a small influence on the magnitude of the signals; however, we have previously published data demonstrating the reproducibility of EMGpara.15 18 Although there was variability in the value of the maximal EMG obtained during the sniff procedure between admission and discharge (see online supplementary figure E2), there was no overall increase during the course of the hospital stay and therefore it is unlikely that the reduction in EMGpara%max between admission and discharge was driven by a fall in the maximal EMGpara.

Clinical applicability of the findings

Readmission within 14 days

Although the cut-off level for ΔEMG_{para/\text{max}} of \(\sim 3.1\%\) has a low PPV for 14-day readmission, the high NPV indicates that NRD has clinical utility as a risk-stratification tool for patients with COPD being discharged from hospital. Patients whose EMG_{para/\text{max}} falls by more than 3.1% during hospital admission are at very low risk of 14-day readmission and indeed these patients have greater time to readmission. The selected cut-off value is similar in magnitude to the fall in EMG_{para/\text{max}} observed amongst non-readmitted patients in the pilot study of Murphy et al., indicating the reproducibility of this technique. Pharmacological and technological therapies could be used in future studies to target a reduction in EMG_{para} with the aim of optimising pulmonary mechanics, which could potentially reduce readmission rates. The cut-off value of \(\sim 3.1\%\) requires further prospective validation to become a useful clinical tool.

Readmission within 28 days

The admission-to-discharge change in NRD failed to predict 28-day readmission across all age groups. This is perhaps unsurprising as several previous studies have shown that age and admission frequency are strongly predictive of readmission. In elderly patients, functional impairment and the burden of chronic disease play a major role in influencing readmission and, in the current study, it appears to be more influential than the failure to enhance the respiratory muscle load–capacity balance. The current data support the concept that the inpatient trajectory of NRD was a key factor influencing 14-day readmission in all age groups and 28-day readmission in those patients less than 85 years of age. Early readmission, under these circumstances, indicates a failure of the inpatient treatment to modify the airways obstruction and lung hyperinflation, and thereby to ameliorate the respiratory muscle load–capacity balance. Future studies should focus on strategies to modify the load–capacity balance and reduce NRD with the aim of promoting safe discharge. The authors acknowledge the limitations of the post-hoc application of an age cut-off of 85 years and wholly appreciate that this is an exploratory analysis and prospective validation will be required to assess 28-day readmission. However, this does not detract from the potential clinical implications of this approach and this analysis ensures that the appropriate target patient group are recruited into any future trials.

Clinical deterioration during admission

We have shown that increases in EMG_{para} predicted worsening of dyspnoea during hospital admission. NRD has the potential to detect worsening dyspnoea and physician-defined clinical deterioration. Second intercostal space parasternal EMG is a novel advanced physiological monitoring tool that may be clinically useful in identifying treatment failure during hospital admission and for predicting safe discharge, which is a priority for all acute healthcare organisations.

CONCLUSION

During recovery from an acute exacerbation of COPD requiring hospital admission, change in NRD from admission to discharge predicted 14-day readmission in all age groups and 28-day hospital readmission in patients under 85 years old. In addition, change in NRD between successive inpatient measurements was able to detect worsening dyspnoea and physician-defined clinical deterioration. Second intercostal space parasternal EMG is a novel advanced physiological monitoring tool that may be clinically useful in identifying treatment failure during hospital admission and for predicting safe discharge, which is a priority for all acute healthcare organisations.

Contributors

Study concept and design: E-SS, PBM, NB, NSH, GR, JM, NH. Acquisition, analysis or interpretation of data: E-SS, SM, MR, RH, MK, KO, KH, AD and NH. Drafting of the manuscript: E-SS, SM, PBM, NH. Critical revision of the manuscript for important intellectual content: RH, MR, MK, AD, MIP, KO, KH, NSH, GR, JM and NH. Statistical analysis: E-SS, SM, AD. Obtained funding: NH. Administrative, technical or material support: SM, RH, MR, KH, KO, GR. Study supervision: NH, JM.

Funding

E-SS and NH acknowledge funding from Guy’s and St Thomas’ Charity, and from Philips Research, for the conduct of this study. MIP’s contribution to the work was supported by the NIHR Respiratory Biomedical Research Unit at the Royal Brompton & Harefield NHS Foundation Trust and Imperial College, who part funded his salary. AD acknowledges financial support from the Department of Health via the National Institute for Health Research (NIHR) Biomedical Research Centre Award to Guy’s & St Thomas’ NHS Foundation Trust in partnership with King’s College London and King’s College Hospital NHS Foundation Trust.

Competing interests

E-SS was in receipt of an unrestricted educational grant from Philips Research to develop physiological monitoring techniques in patients with COPD. MIP reports personal fees from Philips during the conduct of the study. PBM reports travel fees to conferences, lecture fees and hospitality from Philips Respironics, and hospitality from Resmed. JM has a patent US20130310699 A1 pending to Guy’s and St Thomas’ NHS Foundation Trust and King’s College London. NH reports salary contributions made to Guy’s and St Thomas’ NHS Foundation Trust from Philips Respironics during the conduct of the study; salary contribution made to Guy’s and St Thomas’ NHS Foundation Trust, consultancy, lecture fees and unrestricted grants from Philips Respironics outside the submitted work; consultancy, lecture fees and unrestricted grants from Fisher Paykel outside the submitted work; consultancy, lecture fees and unrestricted grants from Resmed outside the submitted work; consultancy, lecture fees and unrestricted grants from B&G Electromedical outside the submitted work; and lecture fees from Linde outside the submitted work; NH has a patent US20130310699 A1 pending to Guy’s and St Thomas’ NHS Foundation Trust and King’s College London.
