Lung irradiation induces pulmonary vascular remodelling resembling pulmonary arterial hypertension

G Ghobadi,1,2 B Bartelds,3 S J van der Veen,1,2 M G Dickinson,3 S Brandenburg,4 R M F Berger,3 J A Langendijk,1 R P Coppes,1,2 P van Luijk1

INTRODUCTION
Pulmonary arterial hypertension (PAH) is a severe and progressive form of pulmonary hypertension that leads to right heart failure and premature death, and no cure is available.1 PAH is characterised by typical angio proliferative lesions, such as neointimal lesions, leading to increased pulmonary vascular resistance.2 The elevated pulmonary vascular resistance leads to high right ventricle systolic pressure and subsequent right ventricular hypertrophy (RVH) ultimately resulting in heart failure.3 4 The pathogenesis of the increased pulmonary vascular resistance is due to a combination of sustained vasoconstriction, arterial wall remodelling and thrombosis.5 Although the typical histopathology of the angio proliferative lesions is well described, the mechanisms are so far unknown. A variety of animal models have been developed to study the mechanism of development and maintenance of pulmonary hypertension. However, few of these models fully describe human PAH.6 Interestingly, we recently showed in a preclinical model that thoracic irradiation also leads to vascular damage, which is the predominant histological change after irradiation of large volumes with a relatively low dose.7 Our findings agreed with suggestions from clinical8 and preclinical studies,9 indicating that treatment of large lung volumes even at a low dose is an important risk factor in the development of pulmonary toxicity. Moreover, whole thoracic irradiation with a sublethal dose was shown to induce increased pulmonary vascular resistance and a decrease in pulmonary arterial distensibility and vascular density early after radiation.10 These features seem similar to those observed in patients with pulmonary hypertension.11 Interestingly, patients already suffering from pre-existing pulmonary vascular disease, manifesting as subclinical increases in pulmonary artery pressure, are known to have an increased risk for radiation-induced pulmonary toxicity.12 However, the type, evolution and consequences of pulmonary vascular remodelling after radiation are largely unknown. In the present study, we hypothesise that vascular damage after irradiation of the lung may develop into PAH. Using high-precision proton radiation beams, this hypothesis was tested by inducing different levels of vascular damage by irradiating small, intermediate and large volumes of rat lungs with graded radiation doses, resulting in an equal risk of inducing pulmonary dysfunction.13 Since vascular damage plays a central role in radiation-
induced pulmonary dysfunction and pulmonary hypertension, we investigated the commonalities between radiation-induced vascular remodelling and previously described PAH models.

**MATERIAL AND METHODS**

**Animals**

Adult male albino Wistar rats (n=78; 270–320 g, 8–9 weeks old) of the Hsd/Cpb:WU strain bred in a specific pathogen-free colony (Harlan-Cpb, Rijswijk, The Netherlands) were used in the experiments. They were housed five to a cage under a 12 h light–12 h dark cycle and fed rodent chow (RMH-B, Hope Farms, Woerden, The Netherlands) and water ad libitum. The experiments were performed in agreement with the Netherlands Experiments on Animals Act (1977) and the European Convention for the Protection of Vertebrate Animals Used for Experimental Purposes (Strasbourg, 18.III.1986).

**Irradiation technique**

To induce different levels of vascular damage, 33%, 50%, 75% or 100% of the rats’ lungs were irradiated to 28, 20/22, 17 and 13 Gy (single fraction) respectively (figure 1). This was done with 150 MeV protons from the cyclotron at the Kernfysisch Versneller Instituut, using the shoot-through technique as published previously.\(^{15–16}\) This results in very sharp lateral field edges (20–80% isodose distance: 1 mm)\(^{16}\) thus sparing the shielded part of the lung very effectively. The irradiation ports (figure 1) were designed using CT scans of animals of the same age and weight.\(^{17}\)

**Histopathology**

For morphological analysis, tissue samples were taken from in-field and out-of-field of the left lung at a distance of at least 3 mm from the field edge and compared with non-irradiated controls (n=3). The radiation response of the pulmonary vasculature was assessed by evaluating the morphology before (2 weeks post irradiation) and at the peak of pulmonary dysfunction (8 weeks post irradiation)\(^{17}\) in three rats per group. Pulmonary sections (5 μm thick) were stained with haematoxylin and eosin, rat endothelial cell (EC) specific marker (HIS52) or Verhoeff’s elastica stain. Since 70% of the pulmonary vascular bed consists of radiosensitive microvasculature,\(^{18–19}\) and damage of these can be expected to have the largest impact on lung function, small intra-acinar vessels (<50 μm) were selected for morphological analysis. For morphometric analysis of the vascular dimensions, lung sections with Verhoeff’s elastica stain were used according to van Albada et al.\(^{20}\) In short, 40 randomly chosen pulmonary intra-acinar vessels <50 μm were assessed at 400× magnification using an image analysis system (CZ KS400; Imaging Associates, Bicester, UK). Two different vascular areas were defined: outer vessel area and luminal area. The outer vessel area was defined as the area within the external elastic lamina. The area within the internal elastic lamina was defined as the luminal area. Areas were transformed into diameters and subsequently wall thickness was defined by subtracting the external diameter from the luminal diameter. Occlusion was then calculated in these pulmonary vessels accordingly, as (outer vessel diameter−luminal diameter)/(outer vessel diameter). Vessels were excluded from the measurement if they were too elliptical (ratio of the largest and smallest diameter exceeded 2), had an incomplete circular shape, were collapsed along more than one-quarter of the vessel wall or were located adjacent to an airway.

**Haemodynamics**

To assess the effect of the early radiation response of the lung vasculature on pulmonary/cardiac haemodynamics, right ventricle and pulmonary artery pressure (RVP and PAP) were directly measured at the peak of pulmonary dysfunction, 8 weeks after lung irradiation, according to Rabino\(v\)itch et al.\(^{21}\) In short, the rats (n=4 per group) first were anaesthetised (isoflurane) and ventilated with room air. A fluid-filled catheter with the pressure transducer was induced via the right external jugular vein into the right ventricle (RV) cavity and guided to the pulmonary artery (PA) under pressure waveform monitoring to record the RVP and PAP. After completion of the haemodynamic measurement, the thorax was opened and heart and lungs were excised. The heart was divided into atria, ventricles and septum and weighted separately. Right ventricle hypertrophy (RVH) was assessed by measuring the ratio of the weights of RV to the combination of left ventricle and intraventricular septum (IVS). The measurements were compared with non-irradiated controls (n=5).

**Breathing rate assay**

In preclinical studies, breathing rate (BR) is considered as a surrogate for pulmonary function.\(^{17–22}\) BR was measured before and every 2 weeks after irradiation up to week 10 (n=24 per group), as previously described.\(^{17}\) The increase in the BR at this time, relative to the mean BR in weeks 0–2 after irradiation, was used as an indicator of early pulmonary dysfunction. The BR of non-irradiated controls was available in our database from previous experiments (n=9).

**Statistics**

To test whether differences exist between groups in pressure measurements and RVH assessment, the post hoc Bonferroni test was performed using one-way analysis if variance. For morphology quantification, the linear mixed model and F-test were specifically used to test differences among quantified parameters when comparing all groups at once. In this test randomly chosen vessels per rat per group were considered as

<th>50% lateral</th>
<th>75%</th>
<th>100%</th>
</tr>
</thead>
</table>
randomly repeated variables. The nominal level of significance was 0.05.

To determine to what extent the changes in BR are explained by changes in PAF, Pearson’s product–moment correlation coefficient of these two parameters was used. A correlation was considered significant if the hypothesis of no correlation was rejected at \( p < 0.05 \). BR varies significantly due to random errors in the measurement. Therefore when using all individual data points for correlation, to answer our main question, the correlation coefficient has to be corrected for attenuation due to the random errors of BR measurement according to the following formula:  

\[
\text{rcorrected} = \frac{\text{rcorrected}}{\sqrt{\text{reliability}_{\text{BR}}}}
\]

The reliability is inversely related to random errors and is the consistency of a set of measurements. To assess the random error in the BR measurement, four random groups of rats with random dose distributions were chosen to resemble the variation in the irradiated population. Their BR measurements during the whole follow-up post irradiation were duplicated, and carried out by the same person. The reliability was then estimated as the concordance correlation coefficient between these two administrations of the same measure and was 0.77.  

**RESULTS**

Global loss of pulmonary endothelial cells precedes parenchymal damage and induces global pulmonary vascular remodelling

At 2 weeks after 50% lung irradiation to 20 Gy, prior to pulmonary dysfunction, the morphology of irradiated and shielded lung tissue was evaluated. In previous work we showed that this irradiation setting results in a comparable level of parenchymal and vascular damage at 8 weeks post irradiation, the peak of pulmonary dysfunction. Indeed, prominent perivascular oedema in large and small vessels was observed in the radiation field (in-field), whereas besides minor changes in the epithelium, no major morphological changes could be observed in the alveolar parenchyma (figure 2A–B). Interestingly, a similar effect was observed in the shielded part of the lung (out-of-field) which received no dose, suggesting a vascular effect throughout the entire lung (figure 2C).

Besides the vascular oedema, loss of cells expressing the rat EC-specific marker HIS52 was observed in-field and out-of-field (figure 2A–C), indicating a global detachment of ECs and disruption of the endothelium in pulmonary vasculature. Since it is well known that changes in the integrity of ECs lead to increased permeability and leakage in irradiated tissues, the early response of pulmonary vasculature to lung irradiation may be initiated from the global lung EC loss. EC injury is a hallmark feature of vascular remodelling was observed without major parenchymal damage (see online supplementary figure 1A). At the peak of pulmonary dysfunction again severe vascular remodelling was observed without major parenchymal remodelling (see online supplementary figure 1B). This may...
indicate that the tolerance dose for vascular response is lower than the parenchymal response.

Global response of pulmonary vasculature is dependent on irradiated volume

Development of pulmonary dysfunction depends on the irradiated lung volume. Therefore, the extent to which pulmonary dysfunction is determined by pulmonary vascular remodelling was assessed by morphological quantification of vascular damage, induced to different levels by irradiating different lung volumes (figure 3C). Strikingly irradiated-volume dependent increases were observed in absolute wall thickness (figure 4B, \(p<0.05\)) and the percentage of luminal occlusion (figure 4C, \(p<0.05\)). Vascular remodelling was more pronounced with an increase in irradiated volume despite the lower radiation dose. Moreover, the out-of-field response increased as the irradiated volume increased (figure 4B,C, \(p<0.05\)). This indicates a global pulmonary vascular response rather than a response confined only to the area where the radiation dose is deposited.

Global pulmonary vasculature response determines pulmonary dysfunction

Global changes in vascular bed increase the pulmonary vascular resistance and induce elevated RVP and PAP, features that are known as pulmonary hypertension. Indeed lung irradiation was found to induce pulmonary hypertension by showing an irradiated-volume dependent increase in all components of RVP and PAP, despite the decreasing dose (figure 5A). Moreover, as can be expected with an increase in pulmonary vascular resistance and PAP, the increased RV workload led to an irradiated-volume dependent RVH and a decrease in IVS weight (figure 5B). These are generally considered as characteristics of the severity of pulmonary hypertension. Therefore the results showed that rats irradiated to the largest lung volume (75%) even to a relatively low dose (17 Gy) suffer from severe pulmonary hypertension. In addition, as a measure of pulmonary function, the BR of the irradiated animals increased in a similar manner to all other measured parameters, indicating that the development of pulmonary dysfunction is related to pulmonary hypertension. To determine to what extent the global pulmonary vascular response and hence pulmonary hypertension are responsible for pulmonary dysfunction, the increase in BR and mean PAP were correlated using all individual data (figure 5C). Remarkably, a strong correlation of these two parameters (figure 5C, \(r=0.9\)) was found. Taken together, our results indicate that the global pulmonary vascular response plays a major role in the development of early radiation-induced pulmonary dysfunction.
DISCUSSION

In preclinical studies pulmonary dysfunction after irradiation of large lung volumes seems to be caused by vascular damage. Since vascular remodelling is a hallmark of PAH, we investigated whether irradiation could induce pulmonary hypertension with the related pulmonary vascular changes.

We show the proof of principle that irradiation of the lung leads to pulmonary vascular remodelling with subsequent pulmonary hypertension and RVH. The pulmonary vascular remodelling induced by irradiation showed striking similarities with the characteristic histopathology of PAH, including EC damage, vascular cell proliferation and neointimal lesions.30 The first signs of vascular changes such as EC loss and perivascular oedema were observed in the irradiated and shielded parts of the lung before any apparent parenchymal or BR changes. Subsequent to global pulmonary vascular remodelling accompanied by PAP elevation, RVH was observed, which is indicative of pulmonary hypertension. This cascade of events was shown to play a major role in the development of BR increase as a surrogate measure for pulmonary dysfunction.

BR is a non-specific measure for pulmonary function. It is only part of the lung function (which is not easily measurable in rats) and changes can be induced by several factors, such as reduced diffusion capacity due to parenchymal damage. However, the very strong correlation between pulmonary hypertension and BR in our study suggests that in our model the reduced ventilatory efficiency as a consequence of reduced perfusion is responsible for the increases in BR, as frequently observed in patients with PAH.31 Hence in this model of PAH in rats, BR may seem to be a sufficient surrogate measure of pulmonary function.

The acute EC loss and perivascular oedema found in the current study may result from ECs detaching from the basal lamina,32 loss of endothelium integrity due to EC retraction and increased permeability to low molecular weight solutes26 shown to occur hours to days after radiation of pulmonary ECs. Although not yet studied in lungs, the importance of acute EC loss in the development of radiation-induced normal tissue damage has been established for other tissues such as intestine, spinal cord and rectum.33–35 In patients treated for rectal cancer with preoperative radiotherapy the radiation injury to normal tissue correlated strongly with the radiation-induced vascular damage as quantified by vascular wall thickness.33 The same study35 also demonstrated that irradiated ECs induce migration and proliferation of vascular smooth muscle cells, an important feature of vascular remodelling in PAH.36 It therefore seems that ECs may be the main target of radiation in many organs and may have a pivotal role in the development of early radiation-induced vascular changes in the lung. However, the current study shows for the first time that this phenomenon can induce pulmonary hypertension and function failure. Indeed in many...
Pulmonary vascular diseases, such as PAH, EC dysfunction is considered to play an initiating role in the pathogenesis of vascular remodelling.27 The features of vascular remodelling in our model show striking similarities with those observed in other experimental pulmonary hypertension models using the same strain of rats of the same age,20 or Sprague Dawley rats with almost the same age and weight (300−350 g).37 38 This supports the hypothesis that EC loss also plays an initiating role in the pathogenesis of the early radiation-induced vascular changes in the lung. Treatment of patients with PAH, in the international classification type I PAH, still have a poor prognosis despite improvement in therapeutic regimens,1 hence it is referred to as the ‘irreversible’ form of PAH.46 47 Irreversibility of pulmonary hypertensive disease has been specifically associated with the presence of these neointimal lesions 50 Although many PAH models have been shown to develop medial hypertrophy, few models have been described that consistently develop neointimal lesions.62 93 74 95 1 In the current era, neointimal models are needed to adequately study the pathobiology of PAH and the effects of new treatment strategies. The occurrence of actual neointimal lesions in this radiation-induced pulmonary hypertension may offer such a novel model. A unique feature of the radiation-induced model is the dependence of irradiated lung volume on the induction of damage52 and consequent changes in PAP (present work), which facilitates well controlled induction to predetermined levels of PAH to study different stages of disease development in a controlled manner.

One of the most striking observations in this model of radiation-induced pulmonary vascular damage is that the histomorphology shows the development of neointimal lesions, which are considered hallmarks of PAH.6 20 46−49 Treatment of patients with PAH, in the international classification type I PAH, still have a poor prognosis despite improvement in therapeutic regimens,1 hence it is referred to as the ‘irreversible’ form of PAH.46 47 Irreversibility of pulmonary hypertensive disease has been specifically associated with the presence of these neointimal lesions 50 Although many PAH models have been shown to develop medial hypertrophy, few models have been described that consistently develop neointimal lesions.62 93 74 95 1 In the current era, neointimal models are needed to adequately study the pathobiology of PAH and the effects of new treatment strategies. The occurrence of actual neointimal lesions in this radiation-induced pulmonary hypertension may offer such a novel model. A unique feature of the radiation-induced model is the dependence of irradiated lung volume on the induction of damage52 and consequent changes in PAP (present work), which facilitates well controlled induction to predetermined levels of PAH to study different stages of disease development in a controlled manner.

Figure 5  Early global response of pulmonary vasculature and the consequent pulmonary hypertension determines radiation-induced pulmonary dysfunction. (A) Pulmonary and cardiac haemodynamics measurement with right-sided cardiac catheterisation at 8 weeks post irradiation showed that all components of right ventricle pressure (RVP) and pulmonary artery pressure (PAP) increase with increasing irradiated volume. s, systolic; d, diastolic; m, mean. (B) The increased workload of the right ventricle (RV) led to irradiated volume-dependent increase in right ventricular hypertrophy (RVH). Left ventricle (LV), RV and intraventricular septum (IVS) weights of all groups are indicated in the table. (C) Early radiation-induced pulmonary dysfunction showed a similar dependence on irradiated volume as assessed by breathing rate (BR) increase. The strong correlation between increase in BR and mean PAP as a readout of global pulmonary vascular remodelling (rcorrected =0.9) indicates that the development of pulmonary dysfunction strongly depends on the global response of lung vasculature. The increases in RVP, PAP and RVH of the irradiated rats were compared with control levels. The outcome for each group was subtracted from the outcome of the control group and then represented in graphs. Data are represented as mean±SEM. A significant difference in measurements of systolic RVP (sRVP), systolic PAP (sPAP), diastolic PAP (dPAP), mean PAP (mPAP), RVH and BR increase among the groups was found, with p values of 0.004, 0.0004, 0.0001, 0.00005, 0.00006 and 0.000003, respectively.
Radiation-induced EC loss (eg, due to apoptosis) and the consequent disruption of endothelial lining with increased permeability and perivascular oedema shown in this model may decrease the blood flow in the irradiated vasculature. As a compensatory effect, the pressure, blood flow and thereby the shear stress would increase in the vasculature in the non-irradiated part of the lungs. This increase of the shear stress may then lead to changes in function and structure of ECs in the non-irradiated vasculature. Indeed, changes in blood flow and shear stress are known to specifically regulate vascular remodelling by altering EC and smooth muscle cell apoptosis and proliferation rates. Increased shear stress induced by increased pulmonary blood flow in patients and animal models with large congenital cardiac shunts is known to lead to pulmonary endothelial dysfunction and progressive vascular remodelling and, thus, flow-associated PAH. This may be a mechanism through which out-of-field EC loss and whole lung vascular remodelling develops. It is expected that irradiation of larger lung volumes even at a low dose (high enough to induce EC apoptosis) induces a more pronounced increase in blood flow and shear stress in non-irradiated vasculatures, leading to an enhanced out-of-field effect. The unique behaviour of our radiation-induced pulmonary hypertension model enables different levels of vascular response to be induced in different parts of the lung and hence may provide opportunities to study the mechanisms involved in progressive vascular remodelling in flow-associated PAH.

So far, treatment for PAH has focused on the use of epoprostenol, phosphodiesterase inhibitors and endothelin receptor antagonists with limited success. Recently, the use of anti-proliferative agents such as imatinib, a platelet-derived growth factor inhibitor, was suggested to be a new class of drugs leading to improved outcome of patients with PAH. Alternatively, cell-based therapies such as the use of bone-marrow-derived endothelial progenitor cells have recently been introduced in experimental PAH and been shown to have a positive effect on pulmonary vascular haemodynamics. For all putative new treatment strategies, however, it is of paramount importance that they show improvements in experimental models mimicking the unique histomorphology of PAH, that is, with neointimal lesions.

CONCLUSION
Lung irradiation was shown to induce pulmonary vascular degeneration and pulmonary hypertension possibly initiated from EC loss. As the histopathology of these lesions closely resembles vascular remodelling in PAH, including neointimal lesions, partial lung irradiation may be a promising new model to study and develop strategies for the prevention and treatment of PAH.
