The UK prevalence of hereditary haemorrhagic telangiectasia and its association with sex, socioeconomic status and region of residence: a population-based study

J W Donaldson,1 T M McKeever,1 I P Hall,2 R B Hubbard,1 A W Fogarty1

ABSTRACT

Background Hereditary haemorrhagic telangiectasia (HHT) is an autosomal dominant genetic disorder of aberrant blood vessel development characterised by arteriovenous malformations. HHT is associated with significant morbidity due to complications including epistaxis, gastrointestinal bleeding and stroke. We explored the hypothesis that a diagnosis of HHT is associated with sex, socioeconomic status and geographical location.

Methods We used The Health Improvement Network, a longitudinal, computerised general practice database covering 5% of the UK population to calculate prevalence estimates for HHT stratified by age, sex, socioeconomic status and geographical location.

Results The 2010 UK point prevalence for HHT was 1.06/10 000 person years (95% CI 0.95 to 1.17) or 1 in 9400 individuals. The diagnosed prevalence of HHT was significantly higher in women compared with men (adjusted prevalence rate ratio (PRR) 1.53, 95% CI 1.24 to 1.88) and in those from the most affluent socioeconomic group compared with the least (adjusted PRR 1.74, 95% CI 1.14 to 2.64). The PRR varied between different regions of the UK, being highest in the South West and lowest in the West Midlands (adjusted PRR for former compared with latter 1.86, 95% CI 1.61 to 2.15).

Conclusions HHT prevalence is more common in the UK population than previously demonstrated, though this updated figure is still likely to be an underestimate. HHT appears to be significantly under-diagnosed in men, which is likely to reflect their lower rates of consultation with primary care services. There is under-diagnosis in patients from lower socioeconomic groups and a marked variation in the prevalence of diagnosis between different geographical regions across the UK that requires further investigation.

INTRODUCTION

Hereditary haemorrhagic telangiectasia (HHT) is an autosomal dominant genetic disorder of blood vessel development characterised by mucocutaneous telangiectases and by arteriovenous malformations in solid organs.1 2 HHT is associated with significant morbidity due to bleeding complications such as epistaxis and gastrointestinal haemorrhage and from embolic complications including cerebral abscess and stroke,3 the latter often due to pulmonary arteriovenous malformations (PAVMs).4 HHT may also be associated with reduced life expectancy.5 6

HHT can be identified by clinical or genetic screening of family members of affected individuals but is too often diagnosed as a result of advanced complications of the disease. A recent expert panel recommended screening all possible or confirmed HHT cases for PAVMs.7 Population-based epidemiological studies in HHT are the essential first step in understanding and quantifying the burden of disease and informing healthcare planning for this under-recognised condition. There are few data regarding differences in geographical prevalence of HHT in the UK or associations with sex, age and socioeconomic status, and this is important as understanding these relations may increase knowledge of factors that modify development and diagnosis of the disease.

Hence, the aim of this study was to determine, using a representative sample of the UK population obtained via an electronic general practice database, a contemporary prevalence of diagnosed HHT and its association with age, sex, geographical location and deprivation status.

Key messages

What is the key question?

▸ What is the current prevalence of hereditary haemorrhagic telangiectasia (HHT) in the UK and how does it vary with respect to age, sex, socioeconomic status and geographical location?

What is the bottom line?

▸ Using a representative UK general practice database we estimate the prevalence of HHT to be at least 1/9500, which is more common than previously documented in the UK, though still likely to represent an underestimate of the true prevalence.

Why read on?

▸ We identify particular under-recognition in the diagnosis of HHT in men and those from less affluent socioeconomic groups, with a significant variation in diagnostic rates between different geographical regions of the UK.
METHODS

Study population
This study utilised an anonymised, computerised, longitudinal general practice database known as The Health Improvement Network (THIN) which has been validated for epidemiological research. The THIN database records a variety of patient clinical and lifestyle data from consultations in primary and secondary care, including medical conditions, symptoms, medications and sociodemographic details. At the time of data extraction (September 2011), THIN covered 5% of the UK population with 3.46 million patients actively followed prospectively from 440 general practices.

Definition of disease
We initially identified all recorded diagnoses (by medical Read codes) between the years 2000 and 2010 of HHT (G770.00) and Rendu–Osler–Weber disease (G770.11). Given the high prevalence of HHT in individuals with PAVMs we also searched for Read codes pertinent to PAVMs (we excluded any individuals previously identified as having Read codes for HHT or Rendu–Osler–Weber disease to prevent double counting). Population denominator values were derived from the annual mid-year populations contributing to THIN. The results presented in this paper are for patients coded as Hereditary HHT (G770.00) or Rendu–Osler–Weber disease (G770.11) only. A repeat analysis of a wider population was conducted, which included all the Read codes listed in table 1.

Statistical methods
Data for 2010 (the most recent complete data year) were used to calculate a point prevalence for HHT. We stratified our results by sex, age group (<15 years, 15–49 years and 50+ years), geographical location and socioeconomic status. Geographical location was defined by UK health authority areas and socioeconomic status was based on the Townsend index score in quintiles. Given the relatively small numbers available for analysis by health authority in 2010, we used combined data from 2000 to 2010 to calculate prevalence estimates for HHT between different health authorities in the UK, adjusting for the use of repeated measures (see below). We were able to look for any significant changes in the prevalence of HHT over the 10-year period between 2000 and 2010. Prevalence estimates taken over multiple years were adjusted by direct standardisation to the 2010 THIN population. Random effects modelling (Huber’s method) allowed for the non-independent nature of the cases contributing each year to the overall disease prevalence estimate, adjusting the SEs of the final model. We used Poisson regression to compare prevalence rate ratios (PRRs), controlling for year, age, sex, Townsend score and health authority. Statistical tests of significance were performed using the likelihood ratio method unless otherwise stated. All analyses were carried out in Stata SE 12 (Stata Statistical Software: Stata/SE V12.0 for Windows; Stata Corporation, College Station, Texas, USA). The research protocol for this study was approved by the THIN Scientific Review Committee.

RESULTS

We identified a total of 563 individuals diagnosed with HHT/ Rendu-Osler-Weber Disease in the THIN database from the years 2000 to 2010 with 365 cases contributing to the calculated point prevalence in 2010. Table 1 presents the total number of diagnosed cases identified in 2010 stratified by Read code.

Overall prevalence
The point prevalence of HHT in 2010 was 1.06/10 000 (95% CI 0.95 to 1.17) or 1/9400. In the sensitivity analysis using broader diagnostic criteria (combining all Read codes from table 1) the point prevalence in 2010 increased to 1.15/10 000 (95% CI 1.04 to .26) or 1/8700.

Prevalence by sex and year
The prevalence of a diagnosis of HHT was strongly related to sex, with a higher prevalence rate in women compared with men for all years between 2000 and 2010 (figure 1). In 2010 the point prevalence in women was 1.29/10 000 person years (95% CI 1.12 to 1.46) and for men was 0.82/10 000 person years (95% CI 0.69 to 0.96). After adjusting for age, deprivation status and geographical location, the PRR in 2010 for HHT was higher in women compared with men (PRR 1.59, 95% CI 1.30 to 1.94, p<0.0001). The prevalence rate for both men and women has remained relatively constant over the last 10 years.

Prevalence by sex and age group
Prevalent cases from 2010 were grouped into three different age categories (<15, 15–49 and 50+ years) and stratified by sex (figure 2). The unadjusted prevalence rate in both sexes was lowest in those aged <15 years and highest in the 50+ age group though the adjusted PRRs across the age groups did not differ significantly (p test for trend=0.29) (table 2).

Prevalence by deprivation status
The prevalence of HHT was inversely associated with socioeconomic deprivation (table 2). The crude prevalence rate in the most deprived group (Townsend score: quintile 5) was 0.68/10 000 (95% CI 0.43 to 0.93) compared with 1.31/10 000 in the least deprived quintile (95% CI 1.07 to 1.55). After adjusting for the effects of age, gender and geographical location, the PRR was higher in those in the least deprived socioeconomic group compared with those in the most deprived group (PRR 1.74, 95% CI 1.14 to 2.64, p<0.0001).

Prevalence by health authority
There was substantial variation in estimates of the crude prevalence of HHT across the UK when stratified by health authority over the 10-year period 2000–2010 (figure 3). The adjusted PRR varied almost twofold across the different UK health authority boundaries (PRR 1.86, 95% CI 1.61 to 2.15, p<0.0001) with the lowest adjusted prevalence in the West Midlands and the highest prevalence in the South West (table 3).
Sensitivity analysis
The above analyses were repeated to include all Read codes listed in table 1, rather than those for HHT and Rendu–Osler–Weber disease alone and revealed no significant differences in qualitative trends of our results or significance values for these trends. There was a slight change in the PRRs calculated for the different health authority areas in the sensitivity analysis, with HHT or PAVMs diagnosed most commonly in Yorkshire rather than the South West (data not shown).

DISCUSSION
Summary of results
This is the first study to use a national primary care population-based database to explore sex, socioeconomic and regional differences in the prevalence of hereditary HHT and provide national prevalence figures for the UK. The 2010 point prevalence for HHT in the UK is 1.06/10 000 (or 1/9400) which has remained relatively stable between 2000 and 2010. The prevalence estimate is higher when Read codes likely to be associated with HHT are included (1/8700) and is higher still if the prevalence in women is considered to be more representative of the population as a whole (1/7800). The prevalence increases with age. The diagnosed prevalence ratio of HHT was 59% higher in women than in men and 74% higher in those from the least deprived socioeconomic group compared with those in the most deprived group. In addition, we have demonstrated a substantial geographical variation in the diagnosed prevalence of HHT across the UK.

Strengths and weaknesses
This is the first population-based study of HHT using a primary care database in the UK general population. With a total of 365 HHT prevalent cases identified in 2010, our study sample size is almost four times larger than the last UK estimate undertaken in 1992,13 is nationally representative and comparable in size with epidemiological studies conducted in other countries.61 41 5 We have been able to stratify our prevalence estimates by sex, age group, deprivation status and geographical location without the risk of bias that may occur either from low response rates (as have been observed in previous surveys of HHT prevalence in the UK13) or from case series in specialist centres which may lack a denominator population or represent cases referred for specialist care with potentially more severe disease.
There are potential limitations to the study which should be addressed. The first is that of the validity of the HHT diagnoses, which are recorded by general practitioners in the THIN database whilst the clinical diagnosis is generally made in secondary care. In practice, we are reasonably confident that the vast majority of these diagnoses will be correct with the increasing involvement of clinical geneticists in the screening and diagnosis of HHT which should result in more reliable information being conveyed to the primary care practitioner, and hence entered into the database. It seems very unlikely that a primary care practitioner would enter a diagnosis of HHT into the database unless it was supported by correspondence from secondary care. The consistency of our calculated prevalence of HHT with other comparable estimates from previous studies also supports the reliability of our data. This score presumes that individuals living within a geographical area have a similar deprivation status which may not be the case. However, there is evidence to suggest that the Townsend scores calculated at a district level are good proxy measures for individual levels of deprivation.19

**Interpretation of results**

Reasons for the marked sex difference between the diagnosed prevalence of HHT require careful consideration. One study from the Dutch Antilles showed a 33% increased prevalence ratio of a ‘definite’ diagnosis of HHT in women compared with men (using the Curacao criteria).15 and a recent US paper found a female:male ratio of 1.54, with HHT being diagnosed more commonly in women.20 Other studies have reported a more balanced distribution between sexes.14 17 Given HHT is an autosomal dominant disorder, the offspring of affected individuals will have a 50% chance of inheriting a mutation and this should not per se be associated with a sex bias. Our data show a significant difference in diagnosis of HHT in women compared with men, which appears to be greatest between the ages of 15 and 49. One possible explanation for this observation is that the higher diagnosed prevalence of HHT in women we observed is due to a difference in access to healthcare resources. Women have significantly higher rates of consultation with primary care providers during the ages of 15–70 years with many consultations due to issues surrounding contraception, pregnancy and childcare, and this may explain an increased ascertainment of symptomatic women with HHT.21 22 A possible alternative explanation for the disparity between sexes may be that the expression of the HHT phenotype is more common in women with the gene mutation. Little is known about the role of other genetic factors (such as moderator genes) or environmental factors that may modify the HHT phenotype but there is limited evidence that symptoms such as epistaxis may be amenable to treatment via manipulation of oestrogen and progesterone levels.23 During pregnancy there is an increased risk of developing complications of HHT24 25 and it has been
suggested that this may represent a modification of the HHT vasculature by female hormones or be secondary to the haemodynamic changes of pregnancy. Clarifying whether the sex differential in diagnosis of HHT is due solely to behavioural factors or may be partly due to biological reasons is an important area for further research.

The reduced prevalence of diagnosed HHT in those from lower socioeconomic groups has multiple potential explanations which encompass controversial issues such as the proximity and quality of healthcare services provided in more deprived areas, and differentials in individuals’ thresholds for accessing these services across different socioeconomic groups. It is internationally recognised that health and healthcare access inequities vary along social gradients and one study looking at health-seeking behaviour in those from more deprived areas with asthma found that these populations reported a higher prevalence of respiratory symptoms but had lower consultation rates for those symptoms. Explanations such as varying access to healthcare, differing perceptions of symptom severity or less positive views of healthcare services were postulated to explain this disparity.

Finally, we observed an almost twofold difference in diagnosed prevalence throughout the UK; least common in the West Midlands and most common in the South West. A pattern of geographical variability has been seen in other studies, most notably in the landmark French paper which first identified a particularly high concentration of affected individuals in the Ain, Jura and Deux-Sevres regions of the country. They attributed their findings to a local founder effect when an initial new mutation had given rise to a cluster of affected individuals that then gradually moved by diffusion to involve other nearby regions. It is not possible to say whether our findings could represent genetic clusters of the disease in the UK or if they are the result of variations in local primary or secondary care recording practice or access to healthcare resources. Further work should try to address this as there may be regions of the UK with a disproportionate under-diagnosis of HHT, thus exposing individuals to the avoidable risk of the complications of this disease.

Figure 3  The crude prevalence of hereditary haemorrhagic telangiectasia (per 10 000) by UK health authority area (2000–2010).
Comparison with existing literature

Table 4 provides a summary of the HHT prevalence estimates of different studies conducted worldwide over the last 25 years. Each study has investigated different populations using different methodologies which, in part, explains the differing results. Certain areas such as the Dutch Antilles and the Ain region of France have shown particularly high prevalence of the disease. Elsewhere, most studies indicate a prevalence between 1 and 1.6/10,000 (or between 1/6000 and 1/10,000) and our study estimate falls within this range, although data from individuals with health insurance in the USA provide estimates as low as 1/33,000.20 Our findings with respect to age are consistent with previous work, with the prevalence of HHT being higher in older age groups, suggesting that the disease has an age-related penetrance17 or alternatively that the likelihood of diagnosis is related to longevity. No other studies have looked at the prevalence of diagnosis by deprivation status and most studies have been restricted to a small geographical area excepting the epidemiological data from France which also show a wide variation in prevalence depending on geographical location.29 31 32 Further research should consider the influence of disease severity on the diagnosed prevalence rate and its potentially confounding effect on our observations with respect to sex, socioeconomic status and geographical location.

Implications

This is the first contemporary study in a representative UK population to estimate the prevalence of HHT and suggests that it is much more common than previously thought, and similar to the prevalence seen in other countries. Assuming that the prevalence of HHT in men is the same as for women, the ‘true’ estimate of total prevalence would be closer to 1.28/10,000 or

*Adjusted for age, sex and Townsend score.
1/7800 (the figure calculated for women alone). A similar approach extrapolating the ‘true’ prevalence from women living in the South West of the UK (the health authority with the highest crude prevalence of HHT) estimates a prevalence of 1.9/10,000 and would equate to at least 11,800 cases of HHT in a population of 62.3 million in 2010. The lower diagnostic rate of HHT in men and those from less affluent social backgrounds suggests a sociological role (or alternatively a biological role) in the presentation of HHT, while the previously unreported regional differences is an observation that requires validation in other datasets. Future research would ideally draw on a national rare disease database with integrated clinical information and genetic samples allowing greater understanding of the presentation of the disease, the genotype–phenotype relationship in HHT and the influences upon it of moderator genes and external environmental factors.
