From the Research Department of Internal Pathology, Department of Internal Medicine, Pneumology Unit (Cliniques Universitaires St-Pierre), and the Bacteriological Institute, University of Louvain, Louvain (Leuven), Belgium

Sputum from patients with various respiratory diseases is known to contain a protein with iron-binding properties (Biserte, Havez, and Cuvelier, 1963) which is absent from the serum and is in all respects identical with a similar red-coloured protein from human milk.

This component was called red milk protein by Johansson (1958), lactosiderophilin by Montreuil, Tonnelat, and Mullet (1960), and lacto-transferrin or lactoferrin by Blanc and Isliker (1961a, b). The last-mentioned name, lactoferrin, seems preferable, since it avoids any confusion between the iron-binding protein from secretions and the structurally unrelated iron-binding protein, transferrin, which occurs in the serum.

Sputum cannot be taken to represent a pure sample of bronchial secretions, since it unavoidably contains some saliva. Since the latter secretion has also been shown to contain lactoferrin (Masson, Carbonara, and Heremans, 1965), the original studies by Biserte *et al.* (1963) left some doubt as to the occurrence of this iron-binding protein in genuine bronchial mucus, although the authors concluded otherwise. However, recent work from our laboratory (Masson, Heremans, and Prignot, 1965b) appears to have shown that lactoferrin does occur among the components of bronchial aspirates collected during bronchoscopy, as well as in bronchial washings obtained during anaesthesia. One of the aims of the present investigation was to confirm the genuine bronchial origin of this protein by demonstrating its presence in the bronchial epithelium and/or its glandular appendages.

The iron-binding protein from the serum, transferrin, is known to display a marked bacteriostatic effect on microbial strains strongly dependent on ionized iron (Schade, 1961). It was

tempting, therefore, to investigate the iron-binding protein from sputum with respect to similar properties. This was the subject of the second part of the present study.

MATERIALS AND METHODS

IMMUNOHISTOCHEMICAL METHODS Specimens from macroscopically normal bronchial areas were obtained from eight patients by biopsy during either bronchoscopy or thoracic surgery. All samples were snap-frozen in dry ice, immediately after removal, and frozen sections were prepared using a Bright-Pearse refrigerated microtome.

Immunohistochemical studies were carried out by means of a fluorescein-conjugated antiserum specifically directed against human lactoferrin (Masson, Heremans, and Prignot, 1965a). This antiserum was obtained from a rabbit which had received a series of intramuscular injections with purified lactoferrin from human milk. Before use, the antiserum was absorbed with normal human serum as well as with human erythrocytes (Rh+, AB). When tested by means of immunoelectrophoresis, the reagent thus obtained proved to be specific for lactoferrin and devoid of any activity against serum proteins or blood-group antigens. The frozen sections were affixed on microscope slides, air-dried, fixated by means of absolute methanol for 3 minutes, washed with two successive baths of buffered saline (pH 7.2), and incubated with a drop of fluorescein-labelled antiserum. After examination under ultraviolet light, the sections were stained by means of the periodic acid-Schiff technique, which earlier experience had proved to be the only satisfactory procedure applicable to such material.

BACTERIOLOGICAL TECHNIQUE Filter paper discs of the type used in routine bacteriological work were soaked in a 0.5% (w/v) solution of lactoferrin isolated from human milk by means of the method described by Blanc and Isliker (1961b). The solvent

FIG. 2. *Pulmonary alveoli showing only dim (yellowish) non-specific fluorescence (calibration 10 μ).*

FIG. 3. Section through a cluster of glandular acini showing bright specific fluorescence characteristic of the presence of lactoferrin (calibration 50 μ).

FIG. 4. Control section stained with antiserum which had been absorbed with lactoferrin. No fluorescence is observed, though many glandular acini are present in this field.

used was a 0.02 M phosphate buffer of pH 7.0. Electrophoretic and immunoelectrophoretic controls proved the lactoferrin used for these experiments to be free of any contaminating proteins with known bacteriostatic effects, such as immunoglobulins, serum-transferrin or lysozyme.

The paper discs were applied on the surface of nutrient agar gel seeded with two species of bacteria, *Staphylococcus albus* and *Staphylococcus aureus*. Bacteriostatic activity was assessed from the size of the area of growth inhibition noted around the discs.

RESULTS

IMMUNOHISTOCHEMICAL LOCALIZATION OF LACTOFERRIN IN BRONCHOPULMONARY STRUCTURES No fluorescence was observed in the epithelial lining from the trachea, the bronchi (Fig. 1) of all sizes, or the bronchioles. The alveolar walls showed only a weak yellowish, non-specific fluorescence under ultraviolet illumination (Fig. 2).

In contrast, bright apple-green fluorescence was present in all glandular acini from all biopsies studied (Fig. 3). The specificity of this fluorescence was proved by the extinction of the reaction after absorption of the antiserum (Fig. 4) by the addition of lactoferrin (2 mg. lactoferrin/ml. fluorescein-labelled antiserum).

From one glandular structure to another, large variations were observed in the intensity and mode of distribution of the specific fluorescence (Figs 5 and 7). In some of the glands practically all the cells had their cytoplasm completely and rather homogeneously filled with strongly fluorescent material. In other glands the fluorescence was restricted to a peripheral seam, whereas a third variety of acini displayed a combination of both modes of distribution. A fourth aspect consisted of a coarsely granular, somewhat streaky, and weaker type of specific fluorescence, with or without a strongly fluorescent peripheral seam.

The interpretation of these findings was assisted by a comparative scrutiny of the same fields, first under ultraviolet light and next by ordinary illumination after application of the periodic acid-Schiff stain (compare Figs 5 and 6, and 7 and 8). Obviously, all parts of acini exhibiting dense filling with strongly fluorescent material consisted of groups of cells displaying the features ordinarily attributed to serous cells (Policard and Galy, 1945). Conversely, wherever a brightly fluorescent peripheral rim was observed in the absence of noticeable centrally located fluorescence, the structure proved to consist of mucous cells. Occasional, peripherally situated patches of

bright fluorescence belonging to otherwise non-fluorescent acini usually turned out to correspond to what is commonly described as 'serous crescents of Gianuzzi'. Weak granular fluorescence was associated with the strongly P.A.S.-positive cytoplasm of spumous and reticular appearance of mucous cells. Absence of fluorescence in the apical part of an acinar cell corresponded either to an optically empty vacuole or to an agglomerate of P.A.S.-positive mucinous material.

BACTERIOSTATIC ACTIVITY OF LACTOFERRIN At the concentration employed (0.5%), lactoferrin clearly inhibited the growth of *Staph. albus* without impairing the development of *Staph. aureus* (Fig. 9).

This inhibitory activity on *Staph. albus* was progressively abolished by the addition of increasing amounts of ionized iron to the lactoferrin solution applied on the discs (Fig. 10).

DISCUSSION

The immunohistochemical data here presented give additional strength to our previous demonstration (Masson *et al.*, 1965b) that lactoferrin is secreted by the bronchial tree. The cellular origin of this protein could be traced to the glandular acini, whereas neither the epithelial lining nor the alveolar walls appeared to take part in its production. Both the serous and mucous cells contained lactoferrin, so that no clearcut functional differentiation between both types seemed warranted on this basis. In serous cells, the lactoferrin was present in large amounts and appeared to be uniformly distributed over the entire cytoplasm. In mucous cells, lactoferrin was largely restricted to the basal part of the cytoplasm, creating the aspect of a brightly fluorescent peripheral rim around the acini predominantly consisting of cells of this type. The apical part of the cytoplasm of mucous cells was either devoid of lactoferrin or contained only moderate amounts of this protein, the latter being anatomically distinct from the strongly P.A.S.-positive mucus.

The bacteriostatic effect of lactoferrin on *Staph. albus* was obvious, although apparently much inferior to that which would be exerted by any of the antibiotics presently in use, employed at similar concentrations. It must be observed, however, that the disc method used here is largely dependent on the diffusion coefficient of the material to be tested. In this respect a substance of large molecular weight (90,000 in the case of lactoferrin) would obviously be at a big disadvantage.

vantage in comparison with a small molecule such as that of a tetracycline. Moreover, no precaution was taken to avoid the presence of iron in the nutrient medium employed for the cultures, so that it may be assumed that the saturation ratio of the lactoferrin was higher in these *in vitro* tests than would be the case in bronchial secretions *in vivo*. For both reasons one may surmise that lactoferrin plays a significant role as a bacteriostatic agent in the secretions where it occurs.

The fact that the inhibitory properties of lactoferrin vanished after the protein had been saturated with iron indicate that the bacteriostatic effect was related to the chelation of ionized iron from the medium, as has been shown by Schade (1961) for serum-transferrin. It is further interesting that both transferrin (Schade, 1961) and lactoferrin inhibited the development of *Staph.*

FIG. 9. Petri dish with left half seeded with *Staph. aureus* and right half with *Staph. albus*. Both paper discs were soaked in a 0.5% lactoferrin solution. Bacteriostatic effect is restricted to *Staph. albus*.

albus but not of *Staph. aureus*, an organism which is known to possess iron-binding receptors with sufficient activity to compete with those of the iron-binding proteins investigated in these experiments.

SUMMARY

Lactoferrin, an iron-binding protein present in bronchial secretions, milk, and saliva but absent from the serum, has been investigated with regard to its site of origin in the bronchial tree. Frozen biopsy sections were incubated with fluorescein-labelled antiserum specifically reacting with lactoferrin. This protein was present in all bronchial glands. Both serous and mucous cells, especially the former, appeared to be involved in the production of lactoferrin.

Purified lactoferrin exhibited a bacteriostatic activity against *Staph. albus* but not against *Staph. aureus*. This effect appeared to be due to the iron-binding properties of the protein, since it could be abolished by supplying an excess of ionized iron to the medium.

This investigation was supported by Grant No. 585 from the Fonds de la Recherche Scientifique Médicale, Brussels, Belgium. The authors are indebted to Dr. F. Meersseman for assistance with the histological work.
