ABSTRACT A histological examination has been carried out on the saphenous veins used in 150 consecutive patients undergoing aortocoronary bypass. Morphological changes were observed frequently and consisted mainly of fibrosis of the intima and of the medial longitudinal muscular layer. Intimal fibrosis was rarely severe enough to narrow the lumen significantly. Statistical analysis disclosed that the fibrosis of the intima and of the medial longitudinal muscular layer do not increase with age. The use of frozen histological sections of the saphenous vein in patients undergoing aortocoronary bypass operations could be considered in order to discard unsuitable grafts and to direct the surgeon to alternative conduits.

The widespread use of autologous saphenous vein for direct myocardial revascularisation procedures is attributable mainly to its easy and safe surgical removal, its almost ideal size and versatility, and its biological acceptance.

While the pathological changes occurring in saphenous vein grafts have been extensively studied,¹⁻¹² very little attention has been paid to the condition of the vein before operation, and the proliferative lesions, observed even early after surgery, have usually been regarded as acquired.

In order to verify the condition of the venous wall before its use as an aortocoronary conduit and to evaluate possible pre-existing morphological changes, a histological survey has been carried out on samples of the same autologous saphenous veins used for the bypass.

Methods

The saphenous vein is removed routinely according to the following technique. The surgeon isolates a segment of vein between the ankle and the knee from one or both legs, through a single incision. Particular care is taken to avoid dissection of the adventitia as well as any trauma to the venous wall and to the saphenous nerve. After all the collateral vessels have been ligated, the vein is removed, washed with heparinised saline,

and briefly stored in it until use.

A histological examination was performed on the same saphenous veins used in 150 consecutive patients undergoing aortocoronary bypass. The patients have been divided into four groups according to age: 21 patients with ages ranging from 35 to 44 years (group A); 76 patients ranging from 45 to 54 years (group B); 45 patients ranging from 55 to 64 years (group C); and eight patients aged more than 65 years (group D).

Multiple segments of the veins were embedded in paraffin and sections of 10 micron thickness were stained with haematoxylin-eosin, Weigert-Van Gieson, and PAS.

Histology of normal saphenous vein

The wall of the human saphenous vein contains a thin intima, separated from the media by a rudimentary internal elastic membrane. The media consists of two distinct layers of muscle cells: an internal longitudinal layer mixed with bundles of collagen and an external circular layer. The adventitia is composed mainly of bundles of collagen with scattered longitudinal fascicles of smooth muscular cells. Near the insertion of the venous valves the longitudinal muscular layer usually becomes thicker.

Results

The main pathological findings consisted of

Fig 1 (a) Saphenous vein wall with grade 1 intimal proliferation and grade 2 sclerosis of the medial muscular longitudinal layer. I=intima; M=media; A=adventitia. Elastic-Van Gieson stain, original magnification $\times 64$. (b) Saphenous vein with grade 3 intimal proliferation. Elastic-Van Gieson stain, original magnification $\times 18$.

various degrees of intimal fibrous thickening, sclerosis of the medial longitudinal muscular layer, and elastosis of the internal elastic lamina (fig 1).

The sclerosis of the inner medial layer, which appears as a replacement process of the muscle elements, has been graded as minimal (grade 1), mild (grade 2), moderate (grade 3), and severe (grade 4).

The intimal fibrosis consisted of an acellular connective tissue proliferation, causing luminal narrowing; it has been classified as grade 1 (focal proliferation with minimal narrowing), grade 2 (concentric proliferation with mild narrowing), grade 3 (concentric proliferation with moderate narrowing—less than 50% of the lumen), and grade 4 (marked narrowing—more than 50% of the lumen).

Only 10 out of 150 veins (6.6%) were free from lesions. One hundred and five (70%) showed intimal fibrosis: grade 1 in 70 (66.6%), grade 2 in

30 (28.7%), and grade 3 in five (4.7%) (fig 2). No patients exhibited a grade 4 intimal fibrosis.

Sclerosis of the medial longitudinal muscular layer was present in 116 out of 150 specimens (77%): grade 1 in 46 (39.6%), grade 2 in 46 (39.6%), grade 3 in 22 (19%), and grade 4 in two (1.7%) (fig 2). Figure 3 shows the distribution of the lesions in the four age groups.

The comparison of the intimal fibrosis in groups A and C, between grades 0 and 3, showed no statistical significance ($\chi^2=0.03$ and 0.04 respectively, $p<0.5$).

Furthermore, the comparison of the fibrosis of the longitudinal muscular layer in groups A and C, between grades 0 and 3, revealed no significant increment with age ($\chi^2=2.47$ and 0.18 , respectively, $p<0.5$).

Discussion

The results of our histological investigation show that morphological changes were present almost constantly in the walls of the fresh "normal" saphenous veins before their use as aortocoronary conduits.

Fig 3 The five degrees of lesion (grades as in fig 2, □ = grade 0) in the 150 saphenous veins, distributed in four age groups.

The main pathological findings consisted of intimal fibrosis, while in the media only the longitudinal muscular layer was involved by the sclerotic process. Although these lesions are usually regarded as an aging process, our statistical analysis revealed that neither the intimal nor the medial sclerosis was correlated with the age of the patients.

The intimal fibrosis was rarely so severe as to reduce significantly the lumen of the vein (five cases with lumen narrowed more than 25%). Nevertheless the condition of the vein should be carefully assessed in each instance in order to discard unsuitable grafts and to direct the surgeon to alternative conduits. In case of doubt, frozen section examination should be considered.

Early and long-term saphenous vein patency depends upon various factors, such as systemic arterial pressure,⁴ distal coronary circulation,¹¹ mural vein ischaemia,¹³ and graft involvement by progressive atherosclerosis.¹⁴⁻¹⁶ The intimal and medial fibrosis observed in the saphenous veins before their use might contribute to the development of progressive proliferation, leading to late graft occlusion.

The pathogenetic importance of this factor will be studied by comparing these histological data with the results of long-term coronary arteriography in these groups of patients, and possibly with specimens removed at reoperation or recovered at necropsy.
