Carbon monoxide diffusing capacity in polycythaemia rubra vera

AP GREENING, K PATEL, AWG GOOLDEN, AJ MUNRO, JMB HUGHES

From the Departments of Medicine and Radiotherapy, Royal Postgraduate Medical School, Hammersmith Hospital, London

ABSTRACT The diffusing capacity of the lung, or transfer factor, for carbon monoxide (TLCO) was measured in 12 patients with polycythaemia rubra vera. This was significantly raised (mean 152% predicted, SEM $\pm$ 14%) and remained so even after correction to a standard haemoglobin concentration of 14.6 g/dl (mean 139% predicted, SEM $\pm$ 13%). Serial measurements of TLCO on two patients after treatment of polycythaemia rubra vera showed a greater fall in relation to haemoglobin concentration than would have been predicted on theoretical grounds if the increases in TLCO had been due entirely to the increased haemoglobin concentration. The pulmonary capillary blood volume (estimated from TLCO) also fell in these two patients after treatment. There was a strong correlation between TLCO and the technetium-99m-labelled red cell volume for the seven men ($r = 0.92$; $p < 0.01$) and five women ($r = 0.99$; $p < 0.001$) when studies were performed on the same day. In patients with polycythaemia rubra vera who have no evidence of coexistent pulmonary disease the pulmonary capillary bed appears to share in the expansion of the body blood volume. The single-breath TLCO test may act as a convenient and simple monitor for the response of the disease to treatment.

The total lung diffusing capacity, or transfer factor, for carbon monoxide (TLCO) is determined by the membrane-diffusing capacity (DM), the reaction rate of carbon monoxide with oxyhaemoglobin (θ), and the pulmonary capillary blood volume (VC). Roughton and Forster¹ proposed the equation

$$\frac{1}{\text{TLCO}} = \frac{1}{\text{DM}} + \frac{1}{\theta \cdot \text{VC}}$$

to describe this relation.

In polycythaemia rubra vera the increased haemoglobin concentration should result in an increase in the reaction rate of carbon monoxide with oxyhaemoglobin, which would lower the red cell resistance and increase the TLCO. Early observations² did not support this prediction but full methodological and clinical details were not given. Later workers have demonstrated an elevated TLCO.^{3,4} Both groups attributed the elevated diffusing capacity to the high haemoglobin concentration. We had observed that some patients with polycythaemia rubra vera had an elevated TLCO even after correction for the high haemoglobin con-

centration. In view of the work of Cotes *et al*⁵ and Clark *et al*⁶ we now routinely correct to a standard haemoglobin concentration of 14.6 g/dl, using the equation:

$$\text{TLCO (corr)} = \text{TLCO (obs)} \cdot \left[\frac{\alpha (\text{Hb}) + \text{Hb}}{(1 + \alpha) \cdot \text{Hb}} \right],$$

where α = DM/VC ratio (assumed to be 0.7), (Hb) = standard haemoglobin concentration (14.6 g/dl), and Hb = the actual haemoglobin concentration. We have therefore studied the TLCO in patients with polycythaemia rubra vera and examined the response to treatment, with particular reference to the membrane conductance (DM) and pulmonary capillary blood volume (VC).

Methods

Twelve patients (seven men and five women) were studied (table 1). Patients 1-7 were studied at first presentation or when they relapsed. Patients 8-12 were studied while receiving maintenance therapy

12	71	F	59	1.50	16.0	39.3	40.4	180
Mean	58		63	1.66	18.8	40.7	50.4	183

(venesection). The diagnosis of polycythaemia rubra vera was made on clinical and haematological criteria.⁷ Pulmonary function tests and measurements of red cell and plasma volumes were performed on all patients on the same day.

Pulmonary function tests—The one-second forced expiratory volume (FEV₁) and the slow vital capacity (VC) were measured on a dry spirometer. Total lung capacity (TLC) was measured in a constant-volume plethysmograph. Predicted values for VC and TLC were taken from Goldman and Becklake.⁸ Alveolar volume (VA) was determined by helium dilution during measurement of the standard single-breath diffusing capacity of the lung for carbon monoxide as set out by Cotes.⁹ TLCO was corrected to a standard haemoglobin concentration (14.6 g/dl) with the formula of Cotes *et al*.⁵; predicted values were taken from Bradley *et al*.¹⁰ With patients 1 and 2 serial pulmonary function tests were carried out after treatment of the polycythaemia rubra vera (by phosphorus-32 and venesection). In addition, TLCO was estimated while they were

breathing room air and 100% oxygen, so that DM and VC could be calculated.¹

Red cell and plasma volumes—The red cell and plasma volumes were determined by the isotopic tracer technique with ^{99m}Tc-labelled red cells and ¹²⁵I-labelled albumin respectively. The results were expressed with reference to standard predicted values.¹¹ The measurements of red cell and plasma volumes were repeated on patients 1, 2, and 6 during a 12-month period.

Results

Pulmonary function test results are shown in table 2. VC, FEV₁/VC ratio, VA, and TLC were normal, but TLCO was significantly raised (mean 152% of predicted, SEM $\pm$ 14%). TLCO remained raised even after correction to a standard haemoglobin concentration (mean 139% of predicted, SEM $\pm$ 13%). Individual results for red cell and plasma volumes are shown in table 1.

A strong correlation was found between TLCO

Table 2 Pulmonary function data for 12 patients with polycythaemia rubra vera at time of first study

Patient No	FEV ₁ /VC (%)	VC (% predicted)	TLC (% predicted)	VA (l BTPS)	KCO (mmol min ⁻¹ kPa ⁻¹ l ⁻¹ BTPS)	TLCO (% predicted)	TLCO (Hb corrected) (% predicted)
1	76	100	93	6.5	2.5	150	131
2	73	97	94	6.3	3.3	200	168
3	78	102	115	6.8	1.9	149	129
4	86	93	90	5.2	2.4	128	116
5	67	93	111	6.6	1.2	100	89
6	63	115	126	8.1	1.0	77	70
7	67	96	100	7.1	1.6	116	100
8	63	85	97	3.2	1.8	190	180
9	80	58	—	2.3	2.2	121	119
10	73	89	—	3.0	2.2	220	207
11	86	85	—	4.7	2.4	150	140
12	76	93	—	3.9	2.0	226	214
Mean	74	92	103	5.3	2.0	152	139

FEV₁ = one-second forced expiratory volume; VC = slow vital capacity; TLC = total lung capacity; VA = alveolar volume; Kco = transfer coefficient; TLco = carbon monoxide diffusing capacity (transfer factor).

Conversion: SI to traditional units—1 mmol min⁻¹ kPa⁻¹ l⁻¹ = 2.99 ml min⁻¹ mm Hg⁻¹ l⁻¹.

Fig 1a Comparison of red cell volume and total lung diffusing capacity of seven men with polycythaemia rubra vera. Results are expressed as percentages of predicted values. Changes after treatment are shown for three patients on whom further measurements were made after 6–12 months.

Fig 1b Comparison of red cell volume and total lung diffusing capacity for five women with polycythaemia rubra vera. Results are expressed as percentages of predicted values.

and the red cell volume, both expressed as percentage of predicted,^{10 11} for the seven men ($r = 0.92$, $p < 0.01$) (fig 1a) and the five women ($r = 0.99$, $p < 0.001$) (fig 1b).

Measurements of DM and Vc on patients 1 and 2 showed that the pulmonary capillary volume was above our laboratory's normal range (50–70 ml). After treatment of their polycythaemia rubra vera the Vc became normal (fig 2).

Discussion

Burgess and Bishop³ and Herbert *et al*⁴ attributed the increased TLCO in their patients with polycythaemia rubra vera to the increased haemoglobin concentration. Our data, however, suggest that it remains raised even after correction

Fig 3 Serial measurements of the total carbon monoxide diffusing capacity of the lung (TLCO) compared with haemoglobin concentration for patients 1 (●) and 2 (○) after treatment of polycythaemia rubra vera. For the two isopleths, corresponding to constant values of DM and Vc (with a DM/Vc ratio of 0.7) (—), the variation in TLCO as haemoglobin concentration alters is a function only of changes in θ . Note that the fall of the patients' TLCO is greater than would be predicted from such isopleths.

Fig 2 Changes in pulmonary capillary blood volume, Vc (-----), and membrane conductance, DM (—), for patients 1 (●) and 2 (○), compared with change in red cell volume, after treatment for polycythaemia rubra vera. Conversion: SI to traditional units— $1 \text{ mmol min}^{-1} \text{ kPa}^{-1} = 2.99 \text{ ml min}^{-1} \text{ mm Hg}^{-1}$.

to a standard haemoglobin concentration of 14.6 g/dl (table 2). This difference may be related to coexistent pulmonary disease since some of the patients of Burgess and Bishop had abnormal pulmonary function tests after treatment of their polycythaemia rubra vera, which the authors interpreted as being consistent with pulmonary thrombotic disease and reduction of the pulmonary vascular bed. On clinical, radiographic, and pulmonary function criteria our patients did not have significant lung disease. The TLCO values are out of proportion to the raised haemoglobin concentration. Serial studies on patients 1 and 2 support this idea. In fig 3 serial values for TLCO during treatment are plotted against haemoglobin concentration. The TLCO fell

at a greater rate in relation to the haemoglobin concentration than would be predicted from the isopleths corresponding to a constant DM and VC. Although the haemoglobin correction factor assumes a DM/VC ratio of 0.7, the correction factor changes by less than 5% if the DM/VC ratio is halved or doubled.

The Roughton-Forster equation¹ predicts that after a correction for the reaction rate (θ) has been made, a further increase in TLCO must be due to an increase in the membrane conductance or capillary blood volume. On theoretical grounds an increase in VC would seem the more likely explanation. Our data on changes in DM and VC following treatment (fig 2) for patients 1 and 2 support this suggestion. Should the pulmonary capillary bed be reduced by pulmonary vascular disease or emphysema, its capacity for expansion is likely to be reduced. In this case the TLCO (corrected) for haemoglobin concentration may show little or no increase when polycythaemia occurs. In one patient with polycythaemia rubra vera who had clinical and radiological¹² evidence of emphysema, the VC was markedly reduced and did not change after treatment for his polycythaemia rubra vera (data not shown). The change in his TLCO after treatment was entirely explained by the change in haemoglobin concentration.

In patients with polycythaemia rubra vera who have no significant pulmonary disease the pulmonary capillary blood volume appears to share the expansion in overall blood volume. Thus the single-breath TLCO test may act as a convenient and

simple monitor for the response of the disease to treatment.
