Aortopulmonary fistula: role of computed tomography

SAM HAMPSON, JOHN PEPPER

From the Cardiothoracic Unit, St George's Hospital, London

Aortopulmonary fistula is an uncommon condition. It may occur as a result of intrathoracic pathology or as a sequel to surgery on the thoracic aorta. Emergency surgical treatment of such fistulas gives poor results and the early recognition of the condition may be life saving. We report a case and discuss the role of computed tomography in establishing the diagnosis.

Case report

A 67 year old man presented with a two month history of haemoptysis—10–20 ml of fresh blood about once a week. Eight years earlier he had undergone elective resection of a saccular aneurysm of the descending thoracic aorta of unknown aetiology. The aneurysm only had been excised and a Dacron onlay patch had been inserted. He had made an uneventful recovery and remained well until October 1985. He gave up smoking at the time of that operation. Physical examination showed a well healed thoracotomy wound but nothing else of note. Routine haematological and biochemical investigations showed no abnormality. A lateral chest radiograph showed mild dilatation of the descending aorta. Bronchoscopy revealed some fresh blood in the left lower lobe posterior basal segmental bronchus. Cytological examination of sputum gave normal results. Computed tomography was performed, 50 ml N. 300am 300 being used as enhancement. This showed an aneurysm of the mid third of the descending aorta (fig 1a) adjacent to a large airway (fig 1b). An aortogram confirmed the presence of a small aneurysm at this site but did not show a fistula.

In view of the continuing haemoptysis we proceeded to an exploratory left thoracotomy on 11 December 1985. Mobilisation of the left lower lobe revealed an area of the posterior basal segment that was densely adherent to a false aneurysm arising from the edge of the original Dacron patch. The lower lobe was separated from the aorta at this point and aorto-aortic bypass established with a 9 mm heparinised Gott shunt. The false aneurysm, Dacron patch, and fistula were excised (fig 2), together with a complete circumference of aorta. The repair was performed with an interposition graft of low porosity Meadox Dacron. A pleural flap was raised to separate the graft from the lower lobe. A small amount of the posterior basal segment was resected with the false aneurysm and the remaining lung repaired with a stapler. The patient made a straightforward recovery and was well and active on review eight months later.

Histological examination of the aorta showed severe ath-

Fig 1 (a) Computed tomography scan of the thorax, which shows a small false aneurysm on the descending aorta. (b) Pulmonary cut showing the proximity of the aneurysm to the bronchus.

Fig 2 Excised Dacron patch and aortic wall to show the site of the fistula at the margin of original patch (indicated by cannula).

eroma with calcification, fibrosis, and loss of the media. There was no appreciable inflammation. The small amount of lung included in the specimen contained haemosiderin and was collapsed.

Discussion

Cases of aortopulmonary fistula are reported as late complications of surgery for persistent ductus arteriosus,¹ coarctation (including that of the first reported fistula), and resection of true or false aneurysm.² Intermittent haemoptysis is the commonest presenting symptom (70% in a collective series³). Delay in diagnosis may result in acute presentation with catastrophic haemorrhage.⁴ The fistulas may, however, be asymptomatic and pain is an unusual feature.⁴

Conclusive diagnosis of the condition preoperatively is difficult. Aneurysmal dilatation is often visible on a plain radiograph and in some cases a pulmonary infiltrate has been described. Da Valle⁴ has warned that bronchoscopy may precipitate serious haemorrhage, but it is difficult to justify the exclusion of this investigation. Most authors are

agreed that aortography, as in this case, contributes little to the diagnosis, but it seems to have been universally used. Computed tomography has been used in more recent cases.^{1,4} Scans may show a mass in the lung parenchyma contiguous with the aorta but no true continuity has yet been demonstrated by contrast enhancement. In this patient the small pouch seen on the lateral wall of the ascending aorta was in close proximity to the bronchus and therefore in the context of the history highly suggestive of a fistula.
