We describe a middle aged man with a predominantly intrapulmonary lymphangioma, which rapidly enlarged and gave rise to persistent haemoptysis of sufficient severity to warrant surgical resection. Radiographic studies showed impairment of venous drainage in the area of the cyst and suggested a mechanism for haemorrhage into the lesion.

Case report

A 54 year old man, an ex-smoker, was noted to have a right hilar mass five years before presentation at our hospital. Thoracotomy had shown a cystic mass (benign lymphangioma on frozen section) enveloping the structures of the right hilum. Resection was not attempted because a pneumonectomy would have been required. A radiograph four years later showed no change.

One month before admission to our hospital he developed a cough and haemoptysis of 30-40 ml a day. Physical examination and laboratory studies revealed no abnormality apart from microcytic anaemia (haemoglobin 11.9 g/dl). Radiologically (fig 1) the mass was larger and contained several air-fluid levels. Fibreoptic bronchoscopy showed distortion and circumferential compression of all lobar and segmental airways of the right lung. Pulmonary angiography showed extrinsic compression of pulmonary arteries and veins; there was no evidence of a systemic arterial supply to the cystic lesion on aortography. Computed tomography with intravenous enhancement by contrast medium showed a multilobulated mass with several air-fluid levels and extrinsic compression of right bronchi, pulmonary arteries, and veins. Venous emptying was delayed. The mediastinal structures were normal.

Because of continued haemoptysis, a right pneumonectomy was performed. At operation a cystic structure was found, intertwined with and enveloping right hilar structures. A cystic appearing lymph node (3.5 × 1.9 × 1.4 cm), not contiguous with the intrapulmonary mass, was resected from the azygous vein and paratracheal area of the mediastinum. In the excised lung multiple cysts (up to 5 cm diameter), many filled with blood clot, were embedded in the hilum and the perihilar parenchyma. The basilar segments of the right lower lobe showed intra-alveolar haemorrhage and haemosiderin laden macrophages. The cysts were lined by flattened endothelium and had varying degrees of

fibroblastic proliferation within their walls, which also contained focal aggregates of lymphocytes without germinal centres, and collections of thin walled, ectatic vascular spaces (fig 2). Similar structures, following the lines of lymphatic sinuses, were observed in the mediastinal node.

Discussion

Adult mediastinal lymphangiomas are congenital anomalies^{1,2} similar to the cystic hygromas usually identified in the perinatal period. They may also be related to cystic lymphangiectasis,³ an almost uniformly fatal condition of neonates affecting predominantly the lung, but also associated with other developmental abnormalities. The cyst walls of lymphangiomas, however, are thicker and more fibrous than those of cystic lymphangiectasis, and adult lymphangioma rarely affects the lung parenchyma.^{4,5} Lymphangioma of both lung and mediastinum has not previously been described, but three cases reported as lymphangiectasis by Wagenaar *et al*⁶ in adolescents may be similar to our case.

Our patient was unusual on two counts. Firstly, the lesion showed no growth for four years, and then more than dou-

bled in size within 12 months. Angtuaco *et al*⁷ described an enlarging mediastinal lymphangioma with prominent vascular elements communicating directly with the innominate vein, but no communication with large vessels could be seen in our patient. Secondly, haemoptysis and lung haemorrhage have not been previously described in association with this lesion. Lymphangiomas frequently have blood within some cysts, presumably because of coexistent haemangiomatic elements, and Ninh and Ninh⁸ reported haemorrhage in 12% of their series of cystic hygroma, highlighting the interrelationship of lymphatic and vascular elements. The dramatic haemorrhage seen in our patient may be related to the obstruction to pulmonary venous outflow shown by angiography and computed tomography. Such obstruction could increase pressure in the vascular components of the tumour. This case shows that intrapulmonary lymphangiomas may not always follow a benign course in adults.
