ABSTRACT There is as yet no convincing evidence that acetazolamide, a carbonic anhydrase inhibitor, is effective in obstructive sleep apnoea. A study was therefore designed to examine the effect of acetazolamide (250 mg/day) on sleep events and ventilatory control during wakefulness in nine patients with the sleep apnoea syndrome. In eight of the nine patients the apnoea index and the total duration of apnoea were reduced by acetazolamide, and the mean (SEM) apnoea index of all patients changed from 25.0 (6.7) to 18.1 (5.8) episodes an hour. Furthermore, the total time of arterial oxygen desaturation (SaO_2)—more than 4% depression in SaO_2 from the baseline sleeping level—divided by total sleep time was also significantly decreased and its mean (SEM) value improved from 24.1 (7.9) to 13.6 (4.8)% of total sleep time. Five of the seven patients with varying degrees of daytime hypersomnolence had their symptoms obviously improved. There was no patient whose predominant type of apnoea was converted from the obstructive to the central type, or vice versa. In the studies of wakefulness, metabolic acidosis, an increase of arterial oxygen tension (PaO_2) and a decrease of arterial carbon dioxide tension (PaCO_2) were observed. The slopes of the occlusion pressure response and the ventilatory response to carbon dioxide increased, and the carbon dioxide ventilatory response line shifted to the left. It is suggested that acetazolamide cannot remove apnoea completely but has a beneficial effect in mild cases of obstructive sleep apnoea through an augmentation of central (CO_2 , H^+) drive and a stabilising effect on ventilatory control.

Owing to insufficient knowledge about the pathogenesis of the sleep apnoea syndrome, effective treatment for most such patients has yet to be established. Current treatment is based merely on the physical findings of the patients, the type of apnoea, and the severity of the syndrome. Drugs such as protriptyline^{1,2} and medroxyprogesterone acetate^{3,4} for obstructive and central sleep apnoea were reported to be effective in only a few patients.

Acetazolamide induces metabolic acidosis by inhibiting carbonic anhydrase in the renal tubular structures and stimulates ventilation. Furthermore, it may increase cerebral carbon dioxide tension (PCO_2) by impeding carbon dioxide transport and may suppress formation of cerebrospinal fluid bicarbonate at the same time, resulting in a sustained increase in alveolar ventilation.

This agent has been used successfully to improve periodic breathing during sleep at high altitude,^{5,6} and was also reported to be useful in central sleep apnoea.⁷ On the other hand, Sharp *et al*⁸ observed that acetazolamide induced metabolic acidosis converted central to obstructive apnoea and worsened hypoxaemia in two patients with mixed apnoea. Shore *et al*⁹ reported a similar case. It remains to be determined therefore whether acetazolamide is useful or not for the treatment of sleep apnoea syndrome, and particularly for the subgroup with obstructive disease.

In the present investigation we have assessed the effect of acetazolamide in patients with sleep apnoea syndrome on indices of sleep disorder and ventilatory control during wakefulness.

Methods

Five men and four women patients with sleep apnoea syndrome were studied (table 1). In most of them polysomnography was performed because of their symptoms—for example, heavy snoring, excessive

daytime sleepiness, and insomniac sensation. The predominant apnoea was the obstructive type, which was present in eight obese patients; one patient (case 7) who had purely central apnoea accompanied by Cheyne-Stokes respiration was not obese. Patients 1 and 3 were mildly hypercapnic, and patients 1 and 4 had chronic obstructive pulmonary disease. Some of the patients were being treated with several drugs that continued to be administered throughout the study. At the time of the study all subjects were clinically stable.

Before administering acetazolamide we performed polysomnography for two consecutive nights, studies of ventilatory control during wakefulness, pulmonary function tests, and arterial blood gas analysis. In the acetazolamide treatment run, 250 mg was given orally once a day and the tests were repeated on the seventh or eighth day of administration.

During the sleep studies surface electrodes were applied to obtain an electroencephalogram (EEG), an electrooculogram (EOG) and a submental electromyogram (EMG). Arterial oxygen saturation (SaO₂) was measured continuously with an ear oximeter (Biox IIA). Movement of the chest wall and abdomen was measured with an inductance plethysmograph (Respirace) and nasal flow with a thermistor. A polygraph was used to record all the variables.

Sleep stages were determined by the criteria of Rechtschaffen and Kales.¹⁰ Apnoea was defined as cessation of flow at the nose for at least 10 seconds. Central apnoea was thought to occur when respiratory effort and airflow were absent, and obstructive apnoea when respiratory effort continued without airflow. Hypopnoea was defined when airflow and respiratory movement were reduced in amplitude by one third, with a depression in SaO₂.¹¹

Resting ventilatory indices, inspiratory minute ventilation (V_I), tidal volume (V_T), respiratory frequency (f), mean inspiratory flow (V_T/T_I) and duty cycle (T_I/T_T) were determined in seven patients while they were

breathing through a mouthpiece. V_T, inspiratory duration (T_I), and expiratory duration (T_E) were electrically displayed by an analogue calculator from the flow signal detected with a hot wire flow meter (Minato RF-H).

Hypoxic and hypercapnic ventilatory responses during wakefulness were measured in seven and eight patients respectively. Hypoxic ventilatory response was determined by an isocapnic progressive hypoxia test. During acetazolamide administration, as the end tidal PCO₂ (P_{ET} CO₂) decreased owing to drug induced hyperventilation, measurement of the hypoxic ventilatory response was made at a P_{ET} CO₂ lower than the pretreatment level. The hypoxic ventilatory response was evaluated from the linear regression between V_I and SaO₂ as well as between mouth occlusion pressure at 0.2 seconds (P_{0.2})¹² and SaO₂, and their response slopes were termed as ΔV_I/ΔSaO₂ and ΔP_{0.2}/ΔSaO₂ respectively. The hypercapnic ventilatory response was measured by Read's rebreathing method, and was evaluated by the slopes of linear regression between V_I and P_{ET} CO₂, as well as between P_{0.2} and P_{ET} CO₂ (ΔV_I/ΔP_{ET} CO₂ and ΔP_{0.2}/ΔP_{ET} CO₂ respectively). Details about the sleep study and the ventilatory response test have been reported previously.^{13 14}

Statistical analysis was performed by paired *t* test after confirmation that the variability within each group was the same.

Results

SYMPTOMS AND SIDE EFFECTS

Five of the seven patients who had varying degrees of daytime sleepiness, the four who felt difficulty in achieving full arousal on awakening, and three of the four who had an insomniac sensation had their symptoms improved to some degree during acetazolamide administration. Though two patients complained of dysaesthesia of the extremities and

another complained of pollakiuria, all patients able to continue taking the drug.

AWAKE RESPONSE

The effects of acetazolamide on arterial blood gas tensions, resting ventilatory indices, and the ventilatory response to hypoxia and hypercapnia during wakefulness are shown in table 2. The acetazolamide treatment produced metabolic acidosis, as shown by the decrease in [HCO₃⁻] and pH. Paco₂ decreased by a mean of 0.9 kPa (6.8 mm Hg) and PaO₂ increased by a mean of 1.6 kPa (12.0 mm Hg). The mean values of $\dot{V}_I$, $\dot{V}_T$, and f during wakefulness increased but their changes were not significant. There was no significant change in the hypoxic responses expressed as $\Delta P_{0.2}/\Delta S_{aO_2}$ and $\Delta \dot{V}_I/\Delta S_{aO_2}$. On the other hand, in the carbon dioxide response study the slopes of the occlusion pressure response ($\Delta P_{0.2}/\Delta P_{CO_2}$) and the ventilatory response ($\Delta \dot{V}_I/\Delta P_{CO_2}$) increased significantly. Furthermore, the mean value of $\dot{V}_I$ at P_{ET} CO₂ 8.0 kPa (60 mm Hg) increased significantly, thereby indicating that the position of the carbon dioxide

ventilatory response line shifted to a lower PCO₂ range.

SLEEP RESPONSE

The total sleep time, sleep efficiency (total sleep time divided by total time in bed), and sleep stage distribution were not altered during acetazolamide treatment (table 3). Before acetazolamide administration the apnoea index (number of episodes/hour of total sleep time) of the nine patients varied from 5.4 to 57.1, with a mean of 25.0 (fig 1). The two patients with an apnoea index below 10 had loud snoring and daytime hypersomnolence. With acetazolamide treatment the mean value of the apnoea index was reduced to 18.1 (range 0.8–43.5). This reduction was significant. Furthermore, the total apnoea time divided by total sleep time also diminished significantly. On the other hand, the number of hypopnoeic episodes per unit sleep time did not change significantly. The mean number of arousals per hour seen on the EEG fell from 7.4 to 4.5.

To assess sleep disturbance, we used the changes of maximal oxygen desaturation during non-REM and REM sleep and the total time of desaturation (more

than 4% depression in SaO_2 from the baseline sleeping level) divided by total sleep time. The baseline and the lowest SaO_2 in REM sleep showed a tendency to increase, but these changes were not significant. The lowest SaO_2 in non-REM sleep, however, increased significantly. Furthermore, the percentage of total desaturation time decreased significantly. This value in the nine patients had varied from 1.0% to 69.2% (mean 24.1%) during the control period, and the improved values were 0.1–42.1% (mean 13.6%) during acetazolamide administration. The apnoea index and apnoea time became worse in case 8. This patient, however, had a diminished desaturation time owing to a considerable reduction in hypopnoeic episodes. On the other hand, in case 6, although the apnoea index decreased, the desaturation time did not change owing to the increase in episodes of hypopnoea. This patient showed a fluttering pattern in the expiratory limb of the flow-volume loop that may have reflected the upper airway obstruction he had while awake.¹⁵

Disordered breathing was most likely to occur in sleep stages 1 and 2 and in REM sleep, except in the patient who had Cheyne-Stokes respiration with periodic apnoea, which considerably decreased during REM sleep. When the effect of acetazolamide in REM sleep and in non-REM sleep was compared, a significant decrease of the apnoea index was observed in each stage (fig 2).

The patients had predominantly obstructive apnoea except for the patient with Cheyne-Stokes respiration,

Fig 2 Changes in apnoea index (number of apnoeic episodes per hour of total sleep time) during non-REM and REM sleep associated with acetazolamide treatment.

but central and mixed types of apnoea were also observed to some extent. In no case was the type of apnoea that predominated induced by acetazolamide.

The changes in the apnoea index, total apnoea time/total sleep time, and desaturation time/total sleep time were not significantly related to changes in the ventilatory and occlusion pressure responses to carbon dioxide during wakefulness. Moreover, they were not correlated with changes in Paco_2 and Pao_2 .

Discussion

We found in this study that acetazolamide reduced but did not remove the episodes of obstructive apnoea and oxygen desaturation during sleep and that it ameliorated clinical symptoms associated with disordered breathing. Acetazolamide has been shown to be effective in two sorts of sleep disordered breathing. Firstly, during acute high altitude exposure acetazolamide was reported to reduce the number of episodes of periodic breathing and improve arterial oxygen saturation.^{5,6} Acetazolamide is known to be useful for the prevention of acute mountain sickness.¹⁶ Secondly, White and colleagues⁷ reported that acetazolamide substantially reduced episodes of central apnoea in all their six patients. Findley *et al*¹⁷ noted that acetazolamide calmed down the oscillations of ventilatory movement and abolished the recurrent episodes of apnoea in Cheyne-Stokes breathing. In contrast, Sharp and colleagues⁸ showed that metabolic acidosis produced by acetazolamide converted central apnoea to obstructive or mixed apnoea. The reason for this remains uncertain, but it may very well be due to the generation of greater negative inspiratory pressure, facilitating upper airway closure. No further reports, however, have appeared to substantiate the evidence of either beneficial or adverse effects of acetazolamide on obstructive sleep apnoea.

The number of apnoeic episodes per hour of total sleep time during the control period varied from 5.4 to 57.1; in two mild cases it was less than 10. The conventional definition for sleep apnoea syndrome—more than five apnoeic episodes an hour—may in fact be an inappropriately small index number for predicting increased health risk or somnolence in subjects over 60 years of age.¹⁸ The two patients with the mild syndrome, however, were a 33 year old man and a 58 year old woman. We therefore diagnosed them as having sleep apnoea syndrome. The mean apnoea index of our subjects was 25.0, indicating a relatively mild sleep apnoea syndrome. The one patient with severe obstructive apnoea treated with acetazolamide but failing to show improvement in oxygen desaturation had the so called “saw tooth” configuration in her expiratory flow-volume curve.¹⁹ In cases where obstructing lesion or abnormality is present in the upper airway it may be difficult to improve the disordered breathing.

In our study one patient who had purely central apnoea did not develop obstructive apnoea with acetazolamide treatment. Önal and colleagues²⁰ found that occlusive and mixed apnoeic episodes occurred at the nadir of periodic fluctuation in diaphragmatic and genioglossal activities, suggesting that both types of apnoea resulted from an instability of ventilatory control during sleep. Their recent report²¹ showed that occlusive sleep apnoea resulted from hypoxia induced periodic breathing in the presence of inspiratory resistive loading in normal volunteers. Remmers and colleagues,²² having studied patients with the Pickwickian syndrome, indicated that the genioglossal electromyogram fluctuated systematically in relation to the periodic breathing cycle: low level activity at the onset of occlusion and prominent discharge at the instant of pharyngeal opening. From these investigations it is suggested that the pathogenesis of obstructive apnoea is related to the instability of ventilatory control in the presence of structural encroachment in the oropharyngeal lumen. Thus administration of an agent capable of producing a stabilising effect on respiratory control may be useful for patients with obstructive sleep apnoea, unless the patient has an obstructive lesion in the upper airway.

In the present study distinctive findings were metabolic acidosis and an augmentation of hypercapnic chemosensitivity during wakefulness after acetazolamide administration. Furthermore, we observed augmentation of minute ventilation at a PCO_2 of 8.0 kPa (60 mm Hg), which indicated left hand shift in the hypercapnic ventilatory response line. We previously confirmed that metabolic acidosis produced by acetazolamide increased ventilation and chemosensitivity to carbon dioxide in healthy men.²³ In this previous study, however, the augmentation of the ventilatory response to carbon dioxide by acetazolamide was larger than that by ammonium chloride induced acidosis and therefore the effect of impeding carbon dioxide transport with a resultant increase in cerebral PCO_2 and $[\text{H}^+]$ might affect carbon dioxide chemosensitivity. If acetazolamide preserved ventilatory stability during sleep and functioned to reduce periodic apnoea, the following factors that may account for improving sleep disorders can be considered. Firstly, a left hand shift of the carbon dioxide response line reduces the tendency for periodic breathing owing to a stabilising effect.²⁴ Secondly, the enhanced ventilation induced by metabolic acidosis reduces hypoxia, and the augmented central (CO_2 , H^+) drive and the relief of hypoxia decrease the relative influence of the hypoxic drive that makes the ventilatory control more unstable than the (CO_2 , H^+) driving system. Several studies suggest that oxygen administration may favourably influence central sleep apnoea.²⁵

During acetazolamide treatment comparison of the hypoxic ventilatory response with the control response was difficult because PCO_2 was depressed by the drug administration. Whether there is an interactive effect between metabolic acidosis and hypoxic chemosensitivity remains to be determined,^{26,27} but our previous study²³ and that of Powles *et al*²⁸ indicated that acetazolamide did not enhance the hypoxic ventilatory response in eucapnic conditions. Another possible mechanism for reducing episodes of apnoea by acetazolamide is alteration of the distribution profile of sleep stages, as was seen after protriptyline.² In our results, however, there was no remarkable change in sleep stages, and acetazolamide reduced sleep apnoea similarly in both non-REM and REM sleep, except in one patient, whose apnoea index increased only in non-REM sleep. A significant increase in lowest Sao_2 was seen in non-REM sleep, whereas a significant improvement in apnoea index was observed in each sleep stage. From these findings it is difficult to believe that acetazolamide had different effects on non-REM and on REM sleep.

To evaluate the effect of a chemical agent on sleep disordered breathing in patients with sleep apnoea syndrome, quantitative measurement appears to be as important for hypopnoeic episodes as for apnoea. In fact, in our study there was one patient whose apnoeic episodes were diminished but hypopnoeic episodes were increased, so that the total desaturation time was not improved. Oxygen desaturation time depends on lung volume (functional residual capacity), baseline Sao_2 , and the number and duration of episodes of apnoea and hypopnoea. Thus the beneficial effects of acetazolamide on sleep apnoea syndrome seem to be reflected by the reduction of desaturation time.

On the other hand, care must be taken regarding the negative effects of acetazolamide. Since it is known that metabolic acidosis affects pulmonary arterial resistance, cardiac contractility, and oxygen transport, this drug should be used only in conjunction with careful control of arterial pH. We used only 250 mg of acetazolamide a day to avoid the development of severe metabolic acidosis. Since mean arterial pH decreased from 7.39 to 7.34 with this dose, the administration of more than 250 mg per day would appear to be unwise. If the depression of bicarbonate concentration develops without concomitant lowering of Paco_2 , the resulting severe metabolic acidosis may endanger some vital organs, and might finally become life threatening.^{29,30}
