Haemothorax caused by a solitary costal exostosis

J R Reynolds, E Morgan

Abstract

A case of spontaneous haemothorax in a 14 year old boy due to trauma to the diaphragm caused by a solitary benign growth (exostosis) of a rib is described.

Exostoses are benign new growths protruding usually from the outer contour of a bone and characteristically capped by growing cartilage. Complications are rare,¹⁻⁵ and only three cases of haemothorax have been reported.^{4,5} We describe a case in which a single costal exostosis caused a sizeable haemothorax.

Case report

A 14 year old schoolboy was referred to hospital with a two week history of pain at the tip of his left shoulder aggravated by deep inspiration and movement. One day before admission to hospital he had a sudden onset of continuous pleuritic left sided chest pain associated with a feeling of light headedness and dyspnoea. There was no history of recent trauma.

He was a tall boy (180 cm), and on examination he was in obvious pain and respiratory distress. His pulse was 110 beats/min and the blood pressure was normal. There was dullness to percussion and reduced breath sounds at the left base. His haemoglobin concentration was 13.5 g/dl. Chest radiography showed a collection of fluid occupying half of the left hemithorax, and pleural aspiration disclosed pure blood (haemoglobin 13.0 g/dl). Cytological examination showed no abnormal cells and Gram stains and cultures showed no microorganisms. Clotting studies gave normal results.

He underwent a left thoracotomy, at which 1500 ml of old blood was evacuated from the left pleural cavity. Initially no obvious source of the bleeding was evident but fresh clot was noted, adherent to the anterior aspect of the left hemidiaphragm adjacent to the insertion of the phrenic nerve. As he was exploring this area the surgeon had his finger pricked by a rose thorn like projection arising from the posterior aspect of the 7th rib. This rib spur projected about 0.8 cm from the deep aspect of the rib, 2.5 cm posterior to the costochondral junction (figure). It was in direct contact with a small area of the diaphragm that was thickened and covered with friable tissue and adherent clot. There were no other abnormalities within the chest or rib cage.

The rib was resected and biopsy samples of

the diaphragm were sent for histological examination. The rib section showed a benign exostosis with minimal cartilage remaining. The biopsy samples of the diaphragm showed vascular cellular fibrous tissue with a chronic inflammatory infiltrate. The patient made an uneventful and full recovery.

Discussion

Exostoses may occur singly as apparent isolated defects or multiply as a congenital disorder (hereditary multiple cartilaginous exostoses). In the multifocal hereditary disorder the lesions occur in infants and children and usually cease to enlarge by puberty. Isolated lesions also occur in infants, but are occasionally found in adults. At least 80% are discovered before the age of 21. Isolated exostosis is found most often on the lower metaphysis of the femur and upper metaphysis of the tibia.

Complications arising from cartilaginous or bony exostoses are uncommon; but central and peripheral nerve compression,¹ popliteal aneurysm,² and traumatic haemarthrosis³ as well as haemothorax^{4,5} have been reported. All three patients with haemothorax, however, had multiple cartilaginous exostoses unlike our patient, whose exostosis appeared to be truly solitary.

In our case (as in the previously reported cases) the sharp edge of the exostosis is likely to have caused direct trauma to the underlying viscera. In the previous cases trauma to the lung and pleura led to relatively minor

Radiograph showing the bony spur projecting from the inner aspect of the resected rib (the spur was fractured during surgery).

haemothoraces, whereas our patient clearly displayed trauma to the surface of the diaphragm and a sizeable haemothorax. Close proximity of the phrenic nerve to the injured area probably explains our patient's shoulder tip pain, which was present for two weeks before his admission. The pain was not present after operation.
