Binding of *Aspergillus fumigatus* spores to lung epithelial cells and basement membrane proteins: relevance to the asthmatic lung

Isabel M J Bromley, Kenneth Donaldson

Abstract

Background – *Aspergillus fumigatus* is an opportunistic pathogen to which asthmatic subjects are particularly susceptible. The ability of spores of *A. fumigatus* to bind to pulmonary cells and basement membrane proteins was investigated to determine the mechanisms involved in this susceptibility.

Methods – Cells of the A549 pulmonary epithelial cell line or purified basement membrane proteins were immobilised on the wells of microtitre plates. They were then exposed to spores of *A. fumigatus* in suspension, with or without various pretreatments of the spores, cells, and proteins. Adherent spores were counted by light microscopy.

Results – Spores of *A. fumigatus* bound in a concentration dependent manner to A549 epithelial cells and pretreatment of cells with interferon γ (2500 units/ml) caused a significant doubling of spore binding. Binding of spores to A549 cells was inhibited by about a third by pre-incubation of the spores with fibrinogen (100 μ g/ml). Spores bound specifically to extracellular matrix (ECM) components laid down by A549 cells, and pretreatment of the ECM components with hydrogen peroxide (25–80 μ M) enhanced spore binding by approximately one third. They also bound specifically and in a saturable manner to purified fibrinogen, fibronectin, laminin, type I collagen, and type IV collagen. Pre-incubation of spores with Arg-Gly-Asp tripeptide (RGD; 50–200 μ g/ml) inhibited binding to fibronectin and type I collagen by 50%.

Conclusions – This study suggests that the presence of activated epithelial cells and the exposure of basement membrane that occurs in asthma, together with oxidant stress, may facilitate the colonisation of the asthmatic lung by *A. fumigatus*. The RGD sequence may be involved in spore binding to some ECM proteins. Free fibrinogen may protect against binding of *A. fumigatus* spores to the pulmonary epithelium.

(Thorax 1996;51:1203–1209)

Keywords: *Aspergillus fumigatus*, spores, asthmatic lung.

Aspergillus fumigatus is an ubiquitous saprophytic fungus with spores of a respirable size

(3 μ m) that are easily dispersed.^{1,2} A high incidence of *A. fumigatus* spores has been noted in human lungs at post-mortem examination relative to other spores of a similar size,³ suggesting that it is able to persist in the lung. In favourable circumstances the spores can establish an infection and/or cause an allergic reaction.² Allergic bronchopulmonary aspergillosis is a disease that predominantly affects asthmatic patients. It is caused by a hypersensitivity response to germinating *A. fumigatus* in the lung and can be serious and even fatal.⁴

The asthmatic lung appears to be particularly susceptible to *A. fumigatus* spores and several studies have reported high rates of sensitivity to *A. fumigatus* in asthmatic subjects. In one study 16% of extrinsic asthmatic subjects reacted to *A. fumigatus*.⁵ In another study of 2080 patients with chest disorders 7% had *A. fumigatus* in their sputum, of which asthma was the predominant disorder compared with bronchitis, bronchiectasis, or pneumonia.⁶ This shows that *A. fumigatus* is present more frequently in asthmatic patients than in those with other respiratory diseases, suggesting that asthmatic airways present a favourable environment to fungal growth which would enhance the likelihood of spore proteins gaining access to immune cells in the interstitium, leading to sensitisation. The same study also reported that 24% of asthmatic patients had positive skin prick tests to *Aspergillus* species.

Deposited spores will inevitably come into contact with the pulmonary epithelium, but little is known of the factors involved in this interaction. We have investigated the binding of *A. fumigatus* spores in experimental conditions that mimic the asthmatic lung – that is, binding to activated pulmonary epithelial cells, basement membrane components, and fibrinogen under conditions of oxidant stress – using the lung type II epithelial cell line A549 as a model air space epithelial cell.

Methods

SPORES OF *ASPERGILLUS FUMIGATUS*

A clinical isolate of *Aspergillus fumigatus* (obtained from Dr Leslie Milne, Department of Mycology, Western General Hospital, Edinburgh) was cultured at 30°C on malt agar. Ten day old spores were harvested by tapping the plates on a surface and by collection into a homogeniser with a spatula. Spores were added to phosphate buffered saline (PBS) pH 7.4 (Gibco, UK), homogenised for two minutes, and then dispersed in a sonic bath for three

minutes to wet the spores and to prevent clumping. The spores were then counted in an Improved Neubauer chamber and a suspension was made up in PBS pH 7.4 at a concentration of 10^6 – 10^7 spores/ml.

CELLS IN CULTURE

Monolayers of the A549 lung epithelial cell line (ECACC) were cultured in Dulbecco's modified Eagle's medium (DMEM; Gibco, UK) supplemented with penicillin (Sigma Chemical Co, UK; 50 000 units/l), streptomycin (Sigma; 50 mg/l) and fetal calf serum (Sigma; 10% v/v); this is called complete DMEM (CDMEM). Cells were cultured at 37°C in an atmosphere of 5% carbon dioxide in air, harvested just before confluence using trypsin with 0.05% (w/v) ethylenediamine tetraacetic acid (Gibco, Paisley, UK), centrifuged for five minutes at 1000 rpm in a bench centrifuge, and resuspended in CDMEM prior to counting in a Neubauer chamber.

BINDING OF *A. FUMIGATUS* SPORES TO A549 CELLS

A549 cells were seeded in 96-well tissue culture plates (Corning, UK) at 10^5 cells per well and grown overnight to confluence in CDMEM at 37°C in an atmosphere of 5% carbon dioxide in air. Plates were washed once in PBS pH 7.4. The following was adapted from the method of Coulot *et al.*⁷ for the assessment of spore binding to immobilised proteins.

The spore suspension (200 µl) was added to each well and the plates were incubated at 37°C in an atmosphere of 5% carbon dioxide in air for 30 minutes with gentle shaking. Plates were washed three times for five minutes in PBS with 0.05% (v/v) Tween 20. The remaining spores were fixed in 2.5% (v/v) glutaraldehyde in PBS for 15 minutes. These spores were counted using a Leitz DM 1L inverted microscope by phase contrast microscopy at $\times 400$ magnification. Five fields of view were counted for each well, in triplicate wells, and the results were expressed as the average number of spores per five high power fields.

BINDING OF SPORES TO A549-DERIVED EXTRACELLULAR MATRIX

A549 cells were seeded and grown overnight as above, then washed once in PBS pH 7.4. Sodium azide at 0.1% (w/v) in distilled water was then added (200 µl per well) and the plates were incubated at room temperature for two hours; 4% (w/v) deoxycholic acid (sodium deoxycholate) in 0.1% (w/v) sodium azide was then added at 200 µl per well and the plates were incubated at room temperature for one hour. This was followed by three washes, each of five minutes, in PBS to remove the cells, as verified by light microscopy, leaving a layer of epithelial cell extracellular matrix (ECECM) coated on the plastic as detected by the Bio-Rad protein assay. In the blocking stage bovine serum albumin (BSA, Sigma) was added to

both the test wells and the control wells at 1 mg/ml in PBS (200 µl per well) and the plates were incubated at 37°C for one hour, then left at 4°C overnight, followed by three washes each for five minutes in PBS. Spores of *A. fumigatus* in suspension in PBS were then added as in the above method.

BINDING OF SPORES TO PURIFIED PROTEINS

The following proteins were used: fibrinogen, fibronectin, laminin, type I collagen, and type IV collagen (all from Sigma). The proteins were dissolved according to the maker's instructions (for example, collagen was dissolved in acetic acid) and then coated onto 96-well flat-bottomed plates (Greiner) as follows: 200 µl protein in PBS pH 7.4 was added to wells at concentrations of 5–500 µg/ml. The plates were incubated at 37°C for one hour, then washed three times in PBS pH 7.4 for five minutes. Plates were blocked in BSA and spore suspensions added as above, after the method of Coulot *et al.*⁷

PRETREATMENT WITH INTERFERON γ

A549 cells were pretreated in interferon γ (IFN- γ) at 1000–2500 units per ml in PBS at 37°C for four hours in an atmosphere of 5% carbon dioxide in air. IFN- γ is known to have an antiproliferative effect on several cell types,⁸ so the number of A549 cells per five fields of view was counted, as well as the number of spores. Results were expressed as the number of adherent spores per 10 cells.

PRETREATMENT WITH HYDROGEN PEROXIDE

Purified proteins, A549 cells, or ECM components laid down by A549 cells were pretreated with hydrogen peroxide (2–80 µM) in PBS at 37°C for three hours.

BLOCKING STUDIES

Spores were pre-incubated with Arg-Gly-Asp tripeptide (RGD; 50–200 µg/ml; Sigma) or with the purified proteins mentioned above (50–500 µg/ml) for 15 minutes at 37°C in a shaking incubator.

STATISTICAL ANALYSIS

Results are expressed as the mean (with one standard error) of triplicate wells in experiments carried out 3–5 times. Data were analysed using the Minitab 8.2 package by one way analysis of variance (ANOVA) and Tukey tests for multiple comparisons. Some data for treated spores and proteins were pooled and compared with non-treated controls by one way ANOVA. Where necessary, data were logarithmically transformed to achieve a normal distribution. The effect of treatment was assessed by the variance ratio (F) test. A p value of <0.05 was considered significant for all tests. Regression analysis was carried out in some experiments.

Figure 1 Adherence of *A. fumigatus* spores (at a concentration of 5×10^6 spores/ml) to A549 cell monolayers after pretreatment of cells with gamma interferon ($\text{IFN-}\gamma$). Results represent mean (SE) spores bound per five high power fields for triplicate wells in three separate experiments and are expressed as the number of adherent spores per 10 cells. Adherence was significantly increased at doses of 1000 units/ml $\text{IFN-}\gamma$ ($p < 0.01$) and above.

Results

BINDING OF *A. FUMIGATUS* SPORES TO A549 CELLS

Spores of *A. fumigatus* adhered in a concentration dependent manner to A549 cells in vitro (data not shown). Pretreatment of A549 cells with $\text{IFN-}\gamma$ (1000–2500 units/ml) caused a significant increase in the number of spores bound per cell at a concentration of 1000 units/ml and above ($p < 0.01$ to $p < 0.001$; fig 1) such that approximately twice the number of spores were bound to cells treated with 2500 units/ml. $\text{IFN-}\gamma$ had no significant antiproliferative effect. Pretreatment of A549 cells with 10–80 μM hydrogen peroxide for three hours had no effect on subsequent spore binding (mean (SE) spores bound per five high power fields for triplicate wells in three separate experiments: control 185.6 (21.3); 10 μM hydrogen peroxide 162.9 (26.9); 80 μM hydrogen peroxide 163.3 (31.4)). Pre-incubation of spores with fibrinogen (100 $\mu\text{g/ml}$) significantly inhibited adhesion ($p < 0.05$). However, as is clear from fig 2, this effect was present only at the two higher spore concentrations where binding was decreased by approximately 30%. The finding of a significant effect across all treatments is a result of the power of the analysis of variance global test. Although PBS incubation was used as a control, fig 3 shows that a control protein (BSA) does not affect binding. The fibrinogen mediated inhibition

Figure 2 Adherence of *A. fumigatus* spores to A549 cell monolayers after pre-incubation of the spores in fibrinogen (100 $\mu\text{g/ml}$). Results are mean (SE) spores bound per five high power fields for triplicate wells in five separate experiments. Spores pre-incubated in fibrinogen adhered significantly less avidly ($p < 0.05$) than control spores pre-incubated in phosphate buffered saline (PBS).

occurred in a dose dependent manner to 50% inhibition at 500 $\mu\text{g/ml}$ compared with BSA, as shown in fig 3. Analysis of variance showed a significant effect of fibrinogen treatment ($p < 0.001$).

BINDING OF SPORES TO A549-DERIVED EXTRACELLULAR MATRIX

Spores adhered to ECECM in a concentration dependent manner ($p < 0.05$) and this binding was more than 10 times greater ($p < 0.001$) than adherence to BSA in all experiments (fig 4). Pre-incubation of spores with RGD at concentrations of 50–200 $\mu\text{g/ml}$ had no significant effect on subsequent spore adherence to ECECM (table 1). Pre-incubation of spores in a control protein had no effect (data not shown). Pretreatment of ECECM with

Figure 3 Adherence of *A. fumigatus* spores (at a concentration of 5×10^6 spores/ml) to A549 cell monolayers after pre-incubation of the spores in fibrinogen. Results represent mean (SE) spores bound per five high power fields for triplicate wells in four separate experiments. Pre-incubation of the spores in the control protein bovine serum albumin (BSA) had no effect on adherence. Spores pre-incubated in fibrinogen adhered significantly less avidly than those pre-incubated in BSA ($p < 0.001$). The fibrinogen regression line had a downward slope significantly different from the horizontal ($p < 0.001$).

Table 1 Spore binding to epithelial cell extracellular matrix (ECECM) or bovine serum albumin (BSA) (1000 $\mu\text{g/ml}$) after pre-incubation of spores in Arg-Gly-Asp tripeptide (RGD)

	RGD ($\mu\text{g/ml}$)			
	0	50	100	200
Adherence to ECECM	572.3(70.1)	570.7(90.7)	540.1(79.9)	508.1(63.5)
Adherence to BSA	17.4(2.0)	31.4(6.0)	28.6(5.6)	35.9(9.7)

Spores were added at a concentration of 5×10^6 per ml. Results are expressed as mean (SE) of spores bound per five high power fields for triplicate wells in three separate experiments.

Figure 4 Adherence of *A. fumigatus* spores to epithelial cell extracellular matrix (ECECM). Results represent mean (SE) spores bound per five high power fields for triplicate wells in three separate experiments. Spore binding to ECECM was significantly higher ($p < 0.001$) than adherence to bovine serum albumin (BSA) in all experiments. Binding increased significantly ($p < 0.05$) as the number of added spores increased.

Figure 5 Adherence of *A. fumigatus* spores (10^6 /ml) to proteins at the indicated concentrations. Results are mean (SE) spores bound per five high power fields for triplicate wells in three separate experiments. Spore binding increased significantly ($p < 0.05$ to 0.001) at and above concentrations of 20 µg/ml for type I and type IV collagen, 50 µg/ml for laminin and fibrinogen, and 100 µg/ml for fibronectin compared with binding to bovine serum albumin (BSA). The dashed line marked BSA shows the minimal spore binding to BSA (1 mg/ml) and the much greater affinity of the spores for extracellular matrix proteins.

25–80 µM hydrogen peroxide for three hours enhanced spore binding compared with untreated cells. Spores were added at a concentration of 5×10^6 per ml. After one-way ANOVA for different doses there was no significant dose effect of hydrogen peroxide, but when all hydrogen peroxide treatments were taken together they were significantly different from all non-hydrogen peroxide treatments (control, 468.8 (50.9); hydrogen peroxide treated, 643.6 (56.9); $p < 0.01$). Binding of spores to BSA amounted to about 5% of binding to ECECM and was not affected by pre-treatment with hydrogen peroxide.

BINDING OF SPORES TO PURIFIED PROTEINS

Spore adherence to purified proteins was significantly higher than adherence to BSA in all experiments ($p < 0.001$) – for example, mean (SE) spores bound per five high power fields with fibrinogen 100 µg/ml was 185 (15) compared with 6 (2) with BSA 1000 µg/ml. Protein dose responses showed that spore binding increased as the protein concentration increased up to a plateau at 100–150 µg/ml (fig 5) for type I collagen, laminin, fibronectin, and fibrinogen; in the case of type IV collagen the curve had not quite levelled out at the highest concentration (200 µg/ml). Spore binding to BSA coated wells (1000 µg/ml) was minimal, as shown by the dashed line in fig 5, and this demonstrates the greater affinity of the spores for ECM proteins.

Protein concentrations on the plateau were chosen for subsequent experiments (200 µg/ml for type IV collagen) in which spores adhered to purified proteins in a spore number dependent manner (data not shown). There was no significant difference in avidity for different proteins. Pre-incubation of spores with RGD had no effect on binding to fibrinogen, laminin, or type IV collagen. Spore binding to fibronectin ($p < 0.01$) and type I collagen ($p < 0.001$), however, was significantly decreased, by more than 50% after RGD pre-incubation (fig 6). Pre-treatment of proteins with hydrogen peroxide (0–80 µM) had no effect on spore adherence (data not shown).

COMPARISON OF SPORE BINDING TO CELLS AND PROTEINS

Figure 7 was composed to give an indication of the range of avidity of spores for different surfaces likely to be found in normal and asthmatic lungs. Spores were found to have increasing avidity as follows: BSA (control protein) (1000 µg/ml) < A549 cells (confluent) < ECECM (from confluent A549 cells) < IFN-γ activated A549 cells (confluent) < purified ECM proteins (average of fibronectin (150 µg/ml), laminin, type I collagen, and type IV collagen (all 100 µg/ml)).

Discussion

This study was undertaken to determine whether asthmatic lungs are more liable than normal lungs to allow the spores of *Aspergillus fumigatus* to attach and persist. The asthmatic lung has activated epithelial cells,⁹ exposed basement membrane resulting from epithelial detachment,^{10,11} and is under oxidant stress from inflammatory cells.^{12,13} The experiments described here set out to mimic these conditions in vitro to quantify *A. fumigatus* spore binding in these circumstances.

Adherence to host epithelium is one of the crucial steps in the pathogenesis of infectious micro-organisms. We have demonstrated for the first time, to our knowledge, the ability of spores of *A. fumigatus* to adhere preferentially to A549 human lung epithelial cells in vitro compared with a control protein. Binding of *A. fumigatus* spores to human type II alveolar

Figure 6 Binding of *A. fumigatus* spores (10^6 /ml) to proteins in a concentration of 100 µg/ml (except fibronectin 150 µg/ml) after pre-incubation with Arg-Gly-Asp tripeptide (RGD) at the indicated concentrations. Results are expressed as mean spores bound per five high power fields for triplicate wells in three separate experiments expressed as a percentage of the values for control spores pre-incubated in phosphate buffered saline (PBS). The standard errors were between one twentieth and one third of mean values. Pre-incubation of spores in RGD had no effect on adherence to bovine serum albumin (BSA), fibrinogen, laminin, or type IV collagen, but it inhibited spore binding to fibronectin ($p < 0.01$) and type I collagen ($p < 0.001$). Spore adherence to purified proteins was significantly higher than adherence to BSA (1000 µg/ml) in all experiments ($p < 0.001$).

Figure 7 Comparison of levels of spore binding to different proteins and cells. Results represent mean (SE) spores bound per five high power fields for triplicate wells in three separate experiments. Activated A549 cells were pretreated with interferon gamma (2500 units/ml). Purified extracellular matrix (ECM) proteins represent the mean values for fibronectin, laminin, type I collagen, and type IV collagen. Spores were added at a concentration of 5×10^6 per ml. BSA = bovine serum albumin; ECECM = epithelial cell extracellular matrix

epithelial cells in primary culture has been previously reported.¹⁴ Spores of *Bacillus subtilis* and sporozoites of *Pneumocystis carinii* adhere to lung epithelial cells which allows colonisation of the mucosa.^{15,16} If the ability shown here of *A. fumigatus* spores to bind to epithelium is reflected in vivo, it could be the first important stage in disease causation, enabling the fungus to persist and to cause tissue damage or allowing allergens to reach the immune system

cells more effectively. Spores of *A. fumigatus* have been shown to produce a diffusible toxin that decreases lung macrophage spreading, respiratory burst, and cytokine production,¹⁷⁻¹⁹ and also inhibits epithelial cell spreading.²⁰ Spores that are attached to epithelial cells, as demonstrated here, would be able to deliver the spore toxin in a more concentrated form, so enhancing its adverse effects. Disruption of the integrity of the epithelial lining could then allow access to the underlying basement membrane and interstitial proteins.

There is evidence of T cell immunity in asthma²¹ with accompanying upregulation of intercellular adhesion molecule 1 (ICAM-1) and other cell surface molecules via cytokines and other mediators of inflammation.^{9,22,23} In an animal model of allergic bronchopulmonary aspergillosis ICAM-1 expression on epithelial cells is enhanced.²⁴ IFN- γ activates epithelial membrane ICAM-1 and MHC class II antigen.^{25,26} In the present study epithelial cell activation with IFN- γ resulted in a marked increase in spore binding and we conclude that the activated epithelium in asthma may be one of the predisposing factors to *A. fumigatus* attachment and colonisation. The putative role of ICAM-1 in the adherence of spores to epithelial cells will be investigated in future work.

Inflammation is present in the asthmatic lung^{27,28} and there is evidence of increased levels of reactive oxygen species released by eosinophils, neutrophils, and macrophages.^{12,13} However, treatment of the epithelium with hydrogen peroxide before exposure to the spores had no effect on spore adhesion.

Spores of *A. fumigatus* bind to fibrinogen²⁹ so we pre-incubated the spores in fibrinogen which inhibited adhesion; incubation in a control protein had no effect. Since fibrinogen specifically blocked binding sites on the spore, we suggest that the cell membrane ligand for spores resembles fibrinogen. Fibrinogen is found in larger quantities in the lungs of asthmatic patients than in normal lungs,^{30,31} so the presence of fibrinogen in the lung air space could be beneficial to the asthmatic host by inhibiting the adhesion of *A. fumigatus* spores.

We used the cells of an alveolar epithelial cell line (A549) in the present study as a model air space epithelial cell. However, we recognise that the epithelial cell type of most direct relevance to asthma is the airway epithelial cell which may differ from alveolar epithelial cells in terms of the responses to spores and to the treatments used here.

Epithelial cells in culture synthesise and secrete ECM glycoproteins including type IV and V collagens, fibronectin, and laminin. In asthma the epithelial lining cells are shed, exposing the underlying basement membrane,^{10,11} and this detachment may result from the action of proteases and oxidants released by local activated leucocytes.³²⁻³⁴ Oxidants such as hydrogen peroxide increase epithelial permeability and decrease cell proliferation,³⁵ which could allow pathogens access to denuded areas for a long period of time due to slow repair.

In the present study *A fumigatus* spores were able to adhere to ECECM components laid down by A549 epithelial cells which was consistently far higher than binding to the control protein BSA. The ability of *A fumigatus* spores to adhere to the basement membrane may confer a further advantage in the asthmatic lung environment.

The RGD tripeptide, which is involved in cell adhesion, was found not to play a part in the binding of spores to ECECM in blocking studies. This may be a result of the complex nature of the ECECM compared with simple purified proteins, or to the process of preparing the ECECM. Pretreatment of the ECECM with hydrogen peroxide to mimic oxidant stress to the ECM that might occur in the asthmatic lung enhanced spore binding, indicating that oxidant stress is an additional factor in spore persistence.

Spores of *A fumigatus* are able to adhere to fibrinogen via a proteinaceous receptor that is not present on hyphae,⁷ and have been reported to bind to laminin.³⁶ In our experiments *A fumigatus* spores adhered to fibrinogen, fibronectin, laminin, type I collagen, and type IV collagen in much greater numbers than to a control protein. Binding of spores to ECM proteins indicates that components of the basement membrane could be the targets for spore binding. Spore adherence to basement membrane proteins was found to be greater than adherence to epithelial cells, indicating increased avidity of spores for epithelium damaged lung. Binding to fibrinogen indicates that spores may be able to adhere to fibrin deposits in the inflamed lung. Pre-incubation of spores with RGD inhibited binding to fibronectin and type I collagen and this suggests that the spores bind to an RGD sequence on these proteins. Since RGD is not available on native collagen but is revealed on denatured collagen,³⁷ our data suggest that there is a degree of denaturation in the type I collagen as supplied. The mycelium of *Candida albicans* has been reported to possess an integrin-like receptor³⁸ and the *A fumigatus* spores may also have such a molecule on their surface. *Candida albicans* also adheres to type I and type IV collagens, fibronectin, and laminin; this is inhibited by fragments of denatured collagen (gelatin) via blockage of fungal adhesins.³⁹ Some pathogenic bacteria also bind to a known site on laminin by mimicking a host epithelial cell receptor.⁴⁰

Figure 7 compares spore binding to different surfaces present in normal and asthmatic lungs. We showed that spores of *A fumigatus* did not have the same avidity for all the surfaces investigated. Binding of spores to surfaces was as follows: purified ECM proteins > activated A549 cells > ECECM > A549 cells > BSA (control protein). These data suggest that the asthmatic lung is an environment that is likely to be more conducive to the adherence and persistence of *A fumigatus* spores than the normal lung. However, fibrinogen may be an important defensive mechanism for protecting the asthmatic lung against *A fumigatus* spores.
