Effect of measurement conditions on measured levels of peak exhaled nitric oxide

C A Byrnes, S Dinarevic, C A Busst, E A Shinebourne, A Bush

Abstract

Background – It is possible to measure nitric oxide (NO) levels in exhaled air. The absolute concentrations of exhaled NO obtained by separate workers in similar patient groups and normal subjects with apparently similar techniques have been very different. A study was undertaken to determine whether changes in measurement conditions alter the concentration of exhaled NO.

Method – NO concentrations measured by a chemiluminescence analyser (Dasibi Environmental Corporation) and carbon dioxide (CO₂) measured by a Morgan capnograph were analysed in single exhalations from total lung capacity in healthy volunteers (mean age 35.9 years). Ten subjects performed five exhalations at four different expiratory flow rates, at four different expiratory mouth pressures, and before and after drinking hot (n=5) or cold (n=5) water. Three subjects performed five exhalations on a day of high background NO (mean NO level 134 ppb) before and after a set of five exhalations made while both the subject and analysers were sampling from a low NO/NO-free reservoir system.

Results – The mean peak concentration of NO decreased by 35 ppb (95% CI 25.7 to 43.4) from a mean (SE) of 79.0 (15.5) ppb at an expiratory flow rate of 250 ml/min to 54.1 (10.7) ppb at 1100 ml/min. The mean peak concentration of NO did not change significantly with change in mouth pressure. The mean (SE) peak NO concentration decreased from 94.4 (20.8) ppb to 70.8 (16.5) ppb (p=0.002, 95% CI 12.9 to 33.1) with water consumption. The mean NO concentration with machine and subject sampling from the low NO reservoir was 123.1 (19.4) ppb, an increase from results obtained before (81.9 (10.2) ppb, p=0.001, 95% CI –19.9 to –62.7) and after (94.2 (18.3) ppb, p=0.017, 95% CI 6.0 to 51.8) sampling with high ambient NO.

Conclusions – The measurement of exhaled NO must be performed in a carefully standardised manner to enable different teams of investigators to compare results. (Thorax 1997;52:697-701)

Keywords: exhalation, nitric oxide, airway inflammation.

and these may reflect airway inflammation.⁴ It has been shown that, when compared with normal subjects, the mean levels of NO in exhaled air are significantly increased in asthmatic subjects who are on bronchodilator therapy as their only treatment.³⁻⁷ Exhaled NO decreases significantly in asthmatic subjects on regular inhaled topical corticosteroids when compared with those on bronchodilator therapy only. Nitric oxide decreases with regular cigarette smoking,^{6,9} with ingestion of alcohol,¹⁰ and may be decreased in subjects with primary ciliary dyskinesia.¹¹ Levels have also been shown to increase with viral upper respiratory tract infections.¹² There is a variation between results seen in men and women with an influence of time of the menstrual cycle affecting the levels obtained in the latter.¹³

However, the absolute mean concentrations of exhaled NO obtained by separate workers in similar patient groups and normal subjects using apparently similar techniques have been quite disparate. In part this could be explained by the different sites of measurement and the degree of contamination of the exhaled air by the nasal and sinus passages. By comparing the concentrations of NO exhaled during tidal breathing through either nose or mouth, Alving *et al*⁶ suggested that the major contribution came from the nasal space with a minor addition from the lower airways. Lundberg *et al*¹¹ demonstrated a decreasing concentration of exhaled NO when sampling progressively down the respiratory tract at the nose, mouth and, in four tracheotomised patients, below the vocal cords. By isolating the nasal passages from the rest of the respiratory tract with voluntary closure of the soft palate Kimberly *et al*¹⁴ showed that the release of NO in the nasal passages was approximately seven times greater than the rest of the respiratory tract. Higher levels have now been demonstrated in the paranasal sinuses with an age dependent increase in keeping with sinus pneumatization.⁹ Gerlach *et al*¹⁵ measured NO concentrations in the nasopharynx and trachea and found higher levels during inspiration than expiration, which suggests that there may be absorption of NO by the lower respiratory tract but does not exclude the possibility of an exhaled component coming from pulmonary synthesis.

The variation in NO levels obtained makes it difficult to compare results presented by different groups. In a preliminary study in normal adult subjects we were able to demonstrate that peak NO concentrations could be halved if subjects exhaled into a T-piece system¹⁶ rather than to the NO analyser directly. The possible variables were flow and mouth pressure. We

It is possible to measure nitric oxide (NO) levels in exhaled air in children and adults¹⁻³

had also noticed a variation in NO signal if the subject drank water before exhaling. Another variable which gives cause for concern is the effect of ambient NO levels on the exhaled concentrations measured. The aim of this study was to test different conditions to see which of these factors (expiratory flow rate, expiratory mouth pressure, water consumption, and background NO concentration) altered the exhaled NO concentrations obtained.

Methods

SUBJECTS

Twenty healthy volunteers (nine men) of mean age 35.9 years (range 18–52 years) took part in the studies. They were non-atopic with no history of respiratory or cardiac disease and were taking no medication. All had normal spirometric values (Compact Vitalograph). Two women smoked two cigarettes per day, the rest were non-smokers.

EQUIPMENT

Exhaled NO was measured on a chemiluminescence analyser (Dasibi Environmental Corporation) adapted for online recording sensitive to concentrations of NO from 2 to 4000 parts per billion (ppb). The NO analyser samples at 240 ml/min with a 95% response time of 6.4 seconds. Carbon dioxide (CO₂) levels were measured with a Morgan capnograph sampling at 200 ml/min with a 95% response time of 141.5 milliseconds. Mouth pressure was measured by a Medex Straingauge pressure transducer through a Gaeltec pressure amplifier in mmHg with a 95% response time of 7.28 milliseconds. Mouth pressure was standardised to 4 mmHg unless otherwise stated. Flow was measured through a Platon flow meter to low flow pneumotachograph and a GM spirometer with a 95% response time of 40.2 milliseconds. The additional flow measurement was made at 225 ml/min unless otherwise stated. NO and CO₂ analysers were calibrated using gas mixtures of known composition. Mouth pressure was calibrated by a MX 1000 pressure transducer. The pneumotachograph was calibrated against known flow rates of air from a cylinder. All calibrations were done before and after each subject was studied. The signal for each of these separate measurements was then displayed on a Linseis chart recorder. When comparing measurements allowance was made for the 2 mm offset of the pens and the time delay for recording of each of the machines.

PROCEDURE

The method and measurement was an adaptation of the previously described technique by Kharitonov *et al.*⁵ Each subject performed five slow exhalations from total lung capacity, made consecutively at three minute intervals for each set of conditions. Nose clips were worn five seconds before the exhalation and taken off between measurements. The subjects abstained from food and drink for four hours

prior to the experiment. The exhaled NO level recorded was the mean peak NO concentration of the five exhalations. In our preliminary experiments,¹⁷ and those of others,⁵ the peak NO concentration has been shown to correlate well with area under the curve. The experiments were made if the ambient level of NO was less than 10 ppb and all inhalation was done from ambient air with the stated exceptions in experiment 4.

Experiment 1: Effect of expiratory flow rate

Ten subjects performed five exhalations at expiratory flows of 250 ml/min, 500 ml/min, 750 ml/min, and 1100 ml/min with a final set of measurements at the first flow to rule out an order effect. Five subjects started with the lowest flow rate and increased their rate with each successive set of five exhalations, and five subjects started with the highest flow rate, decreasing each time. The mouth pressure was kept constant at 4 mmHg by altering a restriction on the flow rotameter which kept this pressure constant at the varying flow rates required.

Experiment 2: Effect of expiratory mouth pressure

Ten subjects exhaled at mouth pressures of 4 mmHg, 8 mmHg, 12 mmHg, and 16 mmHg while maintaining a constant flow of 500 ml/min. This was achieved by altering the restriction in the expiratory tubing at the flow rotameter while the pressure was maintained. Subjects voluntarily maintained the mouth pressure by looking at a pressure gauge. They were randomised to start at the lowest pressure and increase the expiratory pressure with each successive set of five exhalations, or to start at the highest expiratory pressure decreasing each time. All subjects repeated the first set of exhalations at the end of the procedure, as in experiment 1. In a preliminary experiment calibration gas was applied to the NO analyser at pressures from 4 to 40 mmHg by increments of 4 mmHg. Over this range there was an increase in the peak NO signal of 5.6 ppb.³

Experiment 3: Effect of water consumption

Baseline measurements were made in 10 subjects at constant mouth pressure (4 mmHg) and constant flow (500 ml/min). This was followed by measurements made after drinking 60 ml of either hot or cold water (five subjects in each group) 20 seconds prior to exhalation. The subjects then completed a further standard set of five exhalations without any water prior to the manoeuvre.

Experiment 4: Effect of ambient NO level

In three subjects a set of five measurements was carried out by our standard method with constant mouth pressure (4 mmHg) and flow (500 ml/min) with the subject breathing ambient air. This was done during a period when the natural background level of NO was high – above the NO concentration normally meas-

Figure 1 Diagrammatic representation of the reservoir system allowing both machines and subject to sample from a low NO/NO-free air. NO, CO₂, mouth pressure and flow are all measured.

ured on exhalation. The ambient air NO level ranged from 91 to 200 ppb. The next set of measurements was taken with the subject inhaling from a reservoir bag (made of aluminium) filled from a tank of NO-free air (measured NO level 0–2 ppb) (fig 1). The subject exhaled through a one way valve to avoid reservoir contamination and the analysers were sampled from the reservoir system between exhalations. For the measured exhalation the connections were turned so that the subject exhaled to the analysers. At the end of each exhalation the connections were reversed to allow the subject and the analysers to continue to sample from the low NO reservoir. The final set of measurements made were a repeat of the first set (of this experiment) in the standard way with the subject breathing in the known high ambient NO level. In this experiment NO plateaus were the measurement taken.

Approval for the study was obtained from the hospital research ethics committee and informed consent was obtained from each of the subjects.

DATA ANALYSIS

The results were analysed with the SPSS statistical package U 7.0 (SPSS Inc, Chicago, USA) using the Student's *t* test for paired samples. At each level and set of conditions the mean and standard error of the mean (SE) is presented. An analysis of variance for repeated measures was used to determine the effects of flow, mouth pressure, NO background, and before and after water consumption using the subjects as a blocking variable. Differences are represented as means and 95% confidence intervals. The correlation coefficient for NO levels at the increasing expiratory flow rates was calculated for each individual subject and is given for the group as a whole.

Figure 2 Mean peak exhaled NO concentrations at different expiratory flow rates for 10 individuals. Each point is the mean of five exhalations.

Results

Experiment 1: Effects of expiratory flow rate

The mean (SE) peak concentrations of NO at the four expiratory flow rate settings were 79.0 (15.5) ppb at 250 ml/min, 67.8 (13.5) ppb at 500 ml/min, 59.1 (11.2) ppb at 750 ml/min, and 54.1 (10.7) ppb at 1100 ml/min. There were strong linear relations between the NO concentrations obtained at the four flow levels for each individual subject with a correlation coefficient of 0.85 (fig 2). The analysis of variance showed a highly significant difference across the flow rates ($p < 0.001$), with wide variation between the individual subjects. The mean decrease in exhaled NO was 35 ppb (95% CI 25.7 to 43.4) from the expiratory flow rate of 250 ml/min to 1100 ml/min. There were no significant differences in the mean CO₂ levels, mean mouth pressure, or mean duration of exhalation in the measurements made at the differing flow rates. There was no difference between the first baseline and repeated baseline value of NO when the expiratory flow was the same ($p = 0.9$, 95% CI -16.9 to 17.0) excluding an order effect.

Experiment 2: Effect of expiratory mouth pressure

The mean (SE) peak concentrations of NO obtained at the four mouth pressure settings were 61.0 (15.1) ppb at 4 mmHg, 55.2 (12.3) ppb at 8 mmHg, 47.3 (8.4) ppb at 12 mmHg, and 40.1 (7.2) ppb at 16 mmHg. There was no significant difference between the different sets of results. Figure 3 shows that NO levels did not change in most of the patients. However, in two patients who found the higher pressures difficult to sustain there was a fall in NO concentration as mouth pressure increased. There was no difference between the first baseline and repeated final baseline of NO when the mouth pressure was the same ($p = 0.44$, 95% CI -16.7 to 15.6), thus excluding an order effect. There was no significant difference between the rate of flow measured at the different mouth pressure readings. The peak expired CO₂ at different mouth pressure levels tended to decrease. The mean peak values were 5.90 (0.83)% at 4 mmHg, 5.83 (0.82)% at 8 mmHg, and 5.53 (0.95)% at 16 mmHg. There was also a tendency for

Figure 3 Mean peak exhaled NO concentrations at different expiratory mouth pressures for 10 individuals. Each point is the mean of five exhalations.

the duration of exhalation to decrease from 49.9 (4.9) seconds at 4 mmHg, 49.6 (5.6) seconds at 8 mmHg, 44.2 (6.3) seconds at 12 mmHg, to 40.9 (5.5) seconds at 16 mmHg.

Experiment 3: Effect of water consumption

The mean (SE) peak NO concentrations in the 10 subjects was 93.7 (20.8) ppb. This decreased by 23 ppb (95% CI 12.9 to 33.1) to 70.8 (16.5) ppb ($p=0.002$) during the measurements made with the subjects drinking 60 ml of water 20 seconds to five seconds before the exhalation. There was then a significant increase of 17 ppb (95% CI -9.7 to -24.1) to 87.8 (8.7) ppb ($p=0.001$) in the subsequent recordings made in the standard way. There was no difference in the NO concentrations taken before and after the water experiment ($p=0.095$). Water temperature did not affect these findings (data not shown).

Experiment 4: Effect of ambient levels of NO

The background concentration of NO during this procedure was 134.5 (11.9) ppb. The mean (SE) background concentration of the reservoir system was 1 (0.2) ppb. The mean plateau exhaled NO concentration was 123.1 (19.4) ppb in the set of exhalations during which both the machine and subject were sampling from the NO-free reservoir system. This was 41 ppb (95% CI 19.9 to 62.7) greater and 29 ppb (95% CI -6.0 to -51.8) greater than the measurements made, respectively, before and after the reservoir system was used. There was no significant difference in the NO plateaus seen before and after the set of exhalations done with the reservoir ($p=0.27$, 95% CI -10.9 to 35.8).

Discussion

The measurement of exhaled NO is feasible and may reflect airway inflammation.^{1,24} A number of cross-sectional studies of exhaled NO concentrations in different subject groups has been reported. The findings within each research team have been consistent, but the absolute levels of NO between these investigators in the similar subject groups have

been very different. All these investigators used a NO chemiluminescence analyser which, although developed by different companies, had similar sensitivities and regular calibration. The study groups were similar. The measurement of NO taken did vary between mean peak exhaled NO, mean plateau exhaled NO, and NO measured during tidal breathing. This led us to suspect that the technique of measurement critically affected the NO levels obtained.

One area of variability is now thought to be the degree of contamination of exhaled NO by nasal and sinus production. This problem has been investigated by a number of other research groups. The measured NO levels have been found to be greatest in the paranasal sinuses⁹ with an age dependent increase in keeping with sinus pneumatization. A progressive decrease in NO concentration has been found when sampling progressively down the respiratory tract from the nasal passages,^{6,14} oral cavity,¹⁵ and below the vocal cords.¹¹

In a preliminary study on 12 healthy adults¹⁶ we have shown that the concentration of NO obtained could be halved depending on whether the subject was breathing directly into the NO analyser (mean 84.8 ppb) or breathing through a T-piece system (mean 41.2 ppb). This was also true for the 39 normal children studied with the mean direct NO level being 49.6 ppb and the level with a T-piece of 29.7 ppb. The main difference between these two methods was a change in flow from 440 ml/min to 665 ml/min. We therefore designed these studies to determine what factors altered the concentration of exhaled NO obtained.

In the current study changing the expiratory flow rate significantly altered the mean concentration of NO obtained. The higher the flow rate the lower the concentrations obtained. This finding could be explained by assuming that most NO is produced proximal to the alveoli. Thus, analogous to a gaseous phase dye dilution, at high flow rates the proximal NO signal from the upper and lower airways is greatly diluted by NO-free (or at least low NO) alveolar gas. The importance of controlling expiratory flow rates is clear cut.

There were no significant differences between the mean exhaled NO concentrations at 4 mmHg, 8 mmHg, 12 mmHg, and 16 mmHg. There was a trend towards differences between the peak CO₂ levels reached, being 5.90% at 4 mmHg, 5.83% at 8 mmHg, 5.83% at 12 mmHg, and 5.53% at 16 mmHg. This may be accounted for by the differences in the duration of exhalation with 49.9 s at 4 mmHg, 49.6 s at 8 mmHg, 44.2 s at 12 mmHg, and 40.9 s at 16 mmHg. The differences reflect the difficulty for subjects of maintaining exhalation against a strong resistance at constant flow to generate the higher mouth pressures. Subjects found it tiring to maintain and found it difficult to keep their lips tight around the mouthpiece so as not to allow any air to escape when exhaling. In the lower three pressure settings there was no difference in NO, CO₂, flow, or duration of exhalation. The mouth pressure over the likely range encountered has no relevant effects on the measurements in most

individuals but two individuals did show an effect. This suggests the need also to standardise mouth pressure.

Exhaled NO levels measured in the standard way (flow set at 500 ml/min, mouth pressure at 4 mmHg) was 93.7 ppb which decreased significantly to 70.8 ppb when 60 ml of water was drunk between 20 and five seconds before the exhalation. Both the intake of hot and cold water caused a similar decrease in the level of NO. The mechanism of this fall is unknown, but it may be that gut derived NO is responsible for a proportion of the signal.

The background NO concentration is usually low (<15 ppb) but occasionally can be extremely high. In three subjects we showed that there were large differences in the mean exhaled NO concentration obtained depending on the concentration of the NO being inhaled. This finding suggests that measurements of exhaled NO must be done on days with low ambient background NO, or an NO-free circuit should be used such as in our experiment.

The slow expiration time, particularly in the direct measurements, raises the possibility that we are merely recording inspired air contaminated by NO produced from the nose and sinuses and exhaled unchanged. However, use of a faster (T-piece) method does not reveal an abrupt discontinuity suggestive of emptying unchanged dead space prior to measuring true exhaled NO.

In conclusion, several factors critically affect the measured mean peak concentration of exhaled NO. An increase in expiratory flow rate results in a decreased concentration of NO. Although increasing expiratory mouth pressures resulted in no difference in most of the subjects, two showed decreased exhaled NO concentrations. Drinking water just prior to measurement decreases the exhaled NO concentration obtained. A high inspired background level of NO makes the exhaled NO concentrations difficult to interpret. These

findings confirm that the measurement of exhaled NO concentrations in humans must be performed in a standard manner for the levels to have any meaning and to enable different teams of investigators to compare results. These findings may account for some of the discrepant results in the literature.
