ABSTRACT

Background: Bronchial hyperresponsiveness (BHR) and variation in glutathione S-transferase (GST) genes have been associated with asthma risk. The relationship of these two risk factors with adult onset asthma in the general population was investigated.

Methods: *GSTP1* Ile105Val single nucleotide polymorphism and *GSTM1* and *GSTT1* gene deletion polymorphisms were genotyped in the population-representative SAPALDIA cohort. BHR was assessed at baseline by methacholine challenge and defined as a fall of $\geq 20\%$ in forced expiratory volume in 1 s. Independent effects of GST polymorphisms and BHR on new onset of asthma after 11 years of follow-up were estimated by multiple logistic regression analysis, adjusting for relevant baseline measures. Effect modification was assessed by including interaction terms in the model.

Results: Among 4426 asthma-free participants at baseline, 14% had BHR. At follow-up, 3.3% reported new onset of physician-diagnosed asthma. BHR ($p < 0.001$) and *GSTP1* Ile105Val genotype ($p = 0.005$) were independently associated with incident asthma, but no association was seen for *GSTT1* and *GSTM1* gene deletion polymorphisms. Among subjects free of respiratory symptoms at baseline, the effect of BHR on the risk of physician-diagnosed asthma at follow-up was restricted to *GSTP1* 105 Ile/Ile carriers (OR 4.57, 95% CI 2.43 to 8.57 vs 1.40, 95% CI 0.58 to 3.39; p for interaction = 0.023).

Conclusions: If confirmed by independent studies, our results suggest that *GSTP1* Ile105Val genotype strongly determines the progression of BHR to physician-diagnosed asthma in the general population.

Bronchial hyperresponsiveness (BHR) has been recognised as a key feature of asthma,¹ a complex respiratory disorder characterised by chronic airway inflammation, increased mucus formation, airway wall thickening and airway smooth muscle dysfunction. BHR often precedes the development of asthma,^{2–4} but not all subjects exhibiting BHR will develop complete expression of asthma.⁵ Genetic and environmental co-factors may promote or, in contrast, prevent the development of clinically relevant asthma phenotypes among subjects with BHR. Experiments in mice have shown that both airway inflammation and remodelling appear to contribute to the development, progression and persistence of BHR.⁶ Thus, genes expressed in bronchial tissue and involved in the modulation of inflammation and associated oxidative stress represent valid candidate genes likely to

play a role as modifiers of asthma development in subjects with BHR.

Glutathione S-transferases (GSTs) are one group of candidate genes. GSTs are phase II detoxification enzymes involved in the clearing of tobacco smoke-derived and other toxicants.⁷ In addition, they have antioxidative capacities and can affect the systemic and local oxidative stress levels.⁸ *GSTP1* is the GST gene most abundantly expressed in the lungs.⁹ Other highly prevalent GST variants are the homozygous gene deletions of *GSTM1* and *GSTT1* which are associated with lung function in the general population^{10–12} and with respiratory disease.^{13 14}

We have previously reported that baseline BHR—including silent BHR (ie, BHR without concurrent report of respiratory symptoms)—increases the likelihood of an incident asthma diagnosis within 11 years of follow-up in the population-based adult Swiss Study on Air Pollution And Lung and heart Disease In Adults (SAPALDIA) cohort.⁵ We now investigate whether genetic variation in *GSTP1*, *GSTM1* and *GSTT1* modifies the association of BHR with the development of asthma. In particular, a *GSTP1* Ile/Val single nucleotide polymorphism at the amino acid residue 105 results in different enzymatic efficiency.¹⁵ *GSTP1* 105Val heterozygous or homozygous carriers have been shown to experience a protective effect against asthma¹⁶ and atopic airway inflammation.¹⁷ We therefore hypothesised that the risk of an increasing effect of BHR would be stronger among homozygous *GSTP1* 105 Ile carriers and sought to answer this question in a large population-based study.

METHODS

Study population

The SAPALDIA cohort, a prospective multicentre study representative of the adult Swiss general population, investigates environmental and genetic factors determining lung health. Baseline and follow-up examinations 11 years later have previously been described in detail.^{18 19}

Briefly, 9561 subjects predominantly of European Caucasian ethnicity aged 18–60 years were examined at baseline in 1991. Of these, 8047 (84%) agreed to participate fully or partly at the follow-up survey in 2002. Information on health and life style was collected by computer-assisted personal interview at both time points and lung function was evaluated using the same spirometer devices (Sensormedics model 2200, Yorba Linda, USA) at both time points.²⁰ Skin reactivity to eight

common airborne allergens was assessed by skin prick test at baseline. Circulating serum levels of total IgE and Phadiatop test for detection of allergen-specific IgE were measured at baseline using the CAP FEIA system (Pharmacia Diagnostics, Uppsala, Sweden). Blood for DNA extraction and informed consent to genetic testing was collected at follow-up.

Methacholine challenge

BHR was assessed by methacholine challenge (Provocholine, Roche, Nutley, New Jersey, USA) in 7126 participants at baseline. Increasing concentrations of methacholine (0.39, 1.56, 6.25 and 25.0 mg/ml solutions in a phosphate buffer without phenol) were administered through an aerosol dosimeter (Mefar MB3, Bovezzo, Italy).²¹ The presence of BHR was defined as a fall of $\geq 20\%$ in forced expiratory volume in 1 s (FEV₁) up to a cumulative dose of 2 mg (8.37 μ mol). The methacholine responsiveness was determined for each subject by calculating individual dose-response slopes similar to the method suggested by O'Connor *et al.*^{22, 23} The slope was then defined as the ratio between the percentage decline in FEV₁ and the total cumulative dose of methacholine.

Definition of asthma incidence, respiratory symptoms and selected covariates

Incident asthma cases were defined as new asthma reports when participants without asthma at baseline gave a positive answer at follow-up to the following two questions: "Have you ever had asthma?" and "Was this confirmed by a doctor?"

Current asthma symptoms were defined by a self-report of physician-diagnosed asthma and a positive answer to at least one of the following questions: "Are you currently taking any medicine for asthma?" and "Have you had an attack of asthma in the last 12 months?"

Atopy was defined as a positive skin prick test reaction to at least one common allergen tested.²⁴ Occupational exposure to inhalant irritants was assessed by asking: "Have you ever worked in a job which exposed you to vapours, gas, dust or fumes?". Smokers were participants who had smoked ≥ 20 packs of cigarettes or ≥ 360 g of tobacco in their lifetime.^{18, 19, 25} Former smokers at baseline or follow-up were smokers who had quit smoking at least 1 month before the examination. Current smokers reported active smoking at the interview. The amount of cigarette exposure of participants was assessed by pack-years. Environmental tobacco smoke (ETS) was defined by a positive answer to the question: "Have you been regularly exposed to tobacco smoke in the last 12 months? ('regularly' means on most days or nights)?"

Genotyping

Whole blood was sampled at follow-up and DNA was extracted manually¹⁹ using the Gentra Puregene Kit (Gentra Systems, Minneapolis, USA). Genotyping of the *GSTP1* Ile105Val single nucleotide polymorphism and the gene deletion polymorphisms for *GSTM1* and *GSTT1* was performed by TaqMan methodology as previously described.¹² Hardy-Weinberg equilibrium (HWE) for the *GSTP1* Ile105Val polymorphism was tested using Arlequin Version 2.000²⁶ and genotype distribution was found to be in HWE. Genotype frequencies did not differ by Swiss language region or subjects' nationality.

Study sample

We included in the present analysis SAPALDIA participants with valid spirometric and bronchial challenge data from the

baseline examination and questionnaire data who participated in the interview at follow-up ($n = 5825$; see fig 1 in online supplement). Valid information on respiratory health status at baseline and follow-up as well as genotype information on the GST polymorphisms were available for 4682 of these participants. Subjects who had reported physician-diagnosed asthma at baseline were excluded ($n = 256$). The final sample size for this study consisted of 4426 SAPALDIA participants. Missing information for the covariates baseline forced vital capacity (FVC) ($n = 105$), atopy ($n = 99$), pack-years smoked during follow-up ($n = 112$), ETS exposure ($n = 5$) and occupational inhalant exposure ($n = 332$) reduced the study sample available for multiple regression analysis to 3806 subjects, of which 3.1% reported physician-diagnosed asthma for the first time at follow-up ($n = 119$).

Statistical analysis

Differences in genotype frequency between cases and controls were assessed by χ^2 test. The associations between GST genotypes and bronchoconstrictor response slope measured as the percentage fall in FEV₁ per μ mol methacholine at baseline were assessed by multiple linear regression adjusting for baseline information on FEV₁, FEV₁ squared, study area, sex, age, body mass index (BMI), atopy, smoking status and pack-years smoked; predicted values for *GSTP1* Ile105Val genotypes were displayed using the box plot command. The effects of BHR at baseline and GST genotypes on the risk for reporting new physician-diagnosed asthma and current asthma symptoms at follow-up were estimated using multiple logistic regression analysis adjusted for sex, age, study area, baseline measures of FVC and BMI, weight change during follow-up, and follow-up information on smoking status, amount of pack-years smoked, and exposure to ETS, occupational dust, fumes and vapours. Modification of the effect of baseline BHR on incident asthma reports by *GSTP1* Ile105Val genotype was assessed by including a multiplicative interaction term in the model, as well as by stratifying the analysis by genotype. Cumulative asthma incidences with 95% confidence intervals (CI) in subgroups defined by combinations of *GSTP1* Ile105Val genotypes and baseline BHR were calculated using the adjust command after multivariate logistic regression analysis. Two-sided p values of < 0.05 and < 0.10 were considered statistically significant for main effects and interactions.²⁷ All analyses were conducted using STATA SE Version 9.1 (Stata Corporation, Texas, USA).

RESULTS

The characteristics of the study population overall and stratified by the presence or absence of baseline BHR are shown in table 1. Among the 4426 participants free of asthma at baseline, 3.3% ($n = 144$) reported a history of physician-diagnosed asthma at the follow-up examination.

Of the study sample, 14% had BHR at baseline; women were overrepresented in the group exhibiting BHR. Lung function was lower and the proportion of subjects with FEV₁/FVC < 0.70 was higher in the subgroup with BHR. Smokers were more likely to have BHR and the mean amount of pack-years smoked was higher in subjects with BHR, whereas no difference in ETS exposure or occupational exposure to gas, dust and fumes was noted between the two BHR groups. Baseline respiratory symptoms such as wheezing, chronic cough and phlegm and shortness of breath at night were more prevalent in the group with BHR; 19.7% of subjects with BHR reported at least one respiratory symptom compared with only 11.5% of participants

without BHR. The GST genotype distributions agreed well with those previously reported in other Caucasian populations.^{13 16 28}

Earlier reports suggested that *GSTP1* genotype might be associated with BHR.¹⁶ Table 1 shows that the distribution of the various *GSTP1* Ile105Val genotypes was not materially different among participants with or without BHR. Homozygous Ile carriers were slightly underrepresented among subjects with baseline BHR but the difference did not reach statistical significance (44.6% vs 47.2%, $p=0.23$; table 1). We also compared the adjusted

methacholine dose response according to GST genotypes (fig 1). No difference in response to the bronchoconstrictor was observed between the three *GSTP1* Ile105Val genotypes. *GSTM1* and *GSTT1* genotypes were not associated with response to methacholine (data not shown). Homozygous *GSTP1* Ile/Ile genotypes were slightly overrepresented among subjects with asthma at baseline ($p=0.06$). Neither *GSTM1* nor *GSTT1* genotype was associated with self-reported physician-diagnosed asthma at baseline (see table 1 in online supplement).

Figure 1 Distribution of predicted adjusted baseline methacholine dose-response slope in relation to *GSTP1* genotype (adjusted for area, sex, age, baseline information on forced expiratory volume in 1 s (FEV_1), FEV_1 squared, body mass index, atopy, smoking status and pack-years smoked).

In table 2 we present the unadjusted association of both GST genotypes and baseline BHR with physician-diagnosed asthma at follow-up. Both baseline BHR and *GSTP1* Ile105Val genotype—but not *GSTM1* or *GSTT1* gene deletion polymorphisms—were associated with new asthma reports at follow-up ($p < 0.001$ for baseline BHR and $p = 0.005$ for *GSTP1* genotype). The independent associations of baseline BHR and *GSTP1* genotype with physician-diagnosed asthma at follow-up were confirmed after adjustment for potential confounders and mutual adjustment for each other (fig 2). The adjusted odds ratio (OR) for BHR vs no BHR was 3.52 (95% CI 2.31 to 5.35; $p < 0.001$) and for *GSTP1* 105Ile/Ile vs *GSTP1* 105Val genotypes it was 1.71 (95% CI 1.17 to 2.50; $p = 0.006$).

The BHR effect on new reports of asthma and asthma symptoms was modified by *GSTP1* (table 3). The effect of baseline BHR on the risk for new reports of asthma was stronger for the *GSTP1* Ile/Ile genotype (OR 4.84 (95% CI 2.28 to 8.49) vs 2.42 (95% CI 1.25 to 4.67); p for interaction between BHR and *GSTP1* Ile105Val genotype $p_{BHR \times GSTP1} = 0.117$). The effect modification by *GSTP1* genotype reached statistical significance after exclusion of subjects reporting at least one respiratory symptom at baseline (OR 4.57 (95% CI 2.43 to 8.57) vs 1.40 (95% CI 0.58 to 3.39); $p_{BHR \times GSTP1} = 0.023$). Comparable interactions between *GSTP1* genotype and baseline BHR were observed for self-reported asthma symptoms at follow-up. Again, the BHR effect was stronger in homozygous *GSTP1*

Figure 2 Adjusted risk for self-report of physician-diagnosed asthma in relation to baseline bronchial hyperresponsiveness (BHR) as well as *GSTP1* Ile105Val, *GSTM1* or *GSTT1* gene deletion polymorphisms (adjusted for baseline forced vital capacity, body mass index, age, sex, study area, weight change during follow-up, smoking status at follow-up, pack-years smoked to follow-up, environmental tobacco smoke exposure at follow-up, occupational gas/dust/fume exposure at follow-up. BHR effect additionally adjusted for the three GST genotypes; GST genotype effects additionally adjusted for baseline BHR).

Ile/Ile genotypes than in *GSTP1* 105Val carriers and reached statistical significance after exclusion of subjects reporting at least one respiratory symptom at baseline (OR 15.86 (95% CI 5.32 to 47.26) vs 1.95 (95% CI 0.71 to 6.96); $p_{BHR \times GSTP1} = 0.033$). No modification of the BHR/asthma association by *GSTT1* or *GSTM1* gene deletion was observed (data not shown).

The adjusted 11-year cumulative incidence of self-reported physician-diagnosed asthma was 14 cases per 1000 persons (95% CI 9 to 21) among subjects without baseline BHR and no *GSTP1* Ile/Ile genotype; 19 cases per 1000 (95% CI 13 to 28) among subjects without BHR but with *GSTP1* Ile/Ile genotype; 21 cases per 1000 (95% CI 9 to 45) among subjects with BHR and no *GSTP1* Ile/Ile genotype; and 95 cases per 1000 (95% CI 59 to 150) among subjects with both baseline BHR and *GSTP1* 105Ile/Ile genotype. Thus, among participants with baseline BHR in this study population, the excess number of incident asthma cases due to *GSTP1* Ile/Ile genotype was 74/1000 persons over the 11-year follow-up period.

Since GST genotypes have previously been associated with lung growth in children¹⁰ and with lung function in adults,^{12–14} we performed a sensitivity analysis and omitted the adjustment for baseline lung function from all statistical models. None of the effects presented were materially altered (data not shown).

Table 2 Unadjusted association of baseline BHR and GST genotypes with self-report of physician-diagnosed asthma after 11 years of follow-up

DISCUSSION

We present evidence that adults with BHR and *GSTP1* Ile/Ile genotype are at an increased risk of developing asthma. Furthermore, genetic variation in *GSTP1* (but not *GSTM1* or *GSTT1*) modifies the risk of BHR progression to asthma in the general population. As *GSTP1* exhibits the highest lung tissue expression of the three GST enzymes, our results are in line with the hypothesis that the extent of local inflammation in the airways contributes to airway remodelling and thus to the association between BHR and adult onset asthma.

Airway smooth muscle dysfunction^{29–31} and increased airway wall thickening^{32–33} caused by airway remodelling are commonly thought to underlie BHR and possibly its progression to asthma. Prolonged or repeated exposure to airway irritants (such as tobacco smoke, ambient air pollution or occupational activity-derived particles) can cause airway dysfunction of the smooth muscle and the bronchial epithelium through the induction of chronic airway inflammation.^{21–34–35} BHR itself contributes to a harmful circle of sustained inflammation since the associated abnormal airflow resulting from the reduced airway calibre alters the deposition profile of inhalants in the airways.^{36–39} It therefore seems probable that increased depositions of particles with mostly oxidative properties will result in sustained airway inflammation and oxidative stress. This view is corroborated by recent SAPALDIA results showing that BHR increased the effect of ETS exposure on the incidence of asthma-related symptoms.^{3–40}

According to our results, the genetic make-up of a person co-determines the exposure load necessary to induce sustained inflammation, oxidative stress and airway remodelling in the bronchial tissue. The modifying effect of the *GSTP1* Ile105Val genotype may reflect the different (but related) roles of this enzyme (ie, in phase II detoxification of tobacco- or air pollution-derived chemicals,⁷ in oxidant defence⁴¹ and in cell cycle regulation⁴²). Lower *GSTP1* activity in bronchial tissue is likely to result in decreased detoxification of airway irritants, enhanced inflammation and oxidative stress causing sustained airway wall thickening and smooth muscle dysfunction. This

hypothesised pathophysiological mechanism is supported by evidence for the direct involvement of *GSTP1* in the regulation of C-JUN N-terminal protein kinase (JNK) and downstream processes which lead to increased cell proliferation in response to oxidative stress.^{43–44} Mice deficient for *GSTP1* activity are prone to increased tumorigenesis on exposure to polycyclic hydrocarbons.⁴⁵ The modifying effect of *GSTP1* in the BHR/asthma association may therefore result from the central role of this enzyme and oxidative stress in apoptotic processes.

Previous evidence supports the hypothesis that the degree of airway inflammation and oxidative stress contributes to the progression of BHR. First, in utero exposure to maternal smoking increases the risk of progression from BHR to asthma.⁴⁶ Passive smoking has been shown to confer increased oxidative stress locally in bronchial tissue as well as systemically in exposed subjects.^{47–49} Second, obesity characterised by increased systemic inflammation has been associated with increased progression of BHR and asthma.³¹ Third, Cheng *et al*⁵⁰ found a gradient of free radical concentrations in nasal polyps, an inflammatory chronic disease frequently associated with BHR and asthma. Concentrations were lowest in cases with nasal polyps without BHR and asthma, intermediate in those with concurrent silent BHR and highest in cases of nasal polyps with concurrent BHR and asthma.

Genetic GST variants have previously been associated with asthma in different, exclusively cross-sectional, studies. The prevalence of the *GSTP1* 105Val allele was lower in patients with asthma,^{51–52} BHR¹⁶ and asthmatics with severe disease.^{16–17–53–54} Our findings extend this observation and indicate that the *GSTP1* 105Ile/Ile genotype, which is carried by about 47% of our European Caucasian population, represents a prevalent asthma risk factor in the general adult population. The absence of a cross-sectional *GSTP1*/BHR association in our population-based study contrasts with the positive association found by Fryer and colleagues.¹⁶ Their study recruited volunteers and patients from respiratory clinics. Female subjects were overrepresented (>70%). Women are known to be more susceptible to bronchoconstrictor challenge^{16–23} although, in

the SAPALDIA cohort, the *GSTP1*/BHR association was not modified by gender (data not shown). Our finding of a lack of association between *GSTM1* and *GSTT1* gene deletion and the occurrence of asthma also contrasts with some previous results. A few small case-control studies suggest that the prevalence of *GSTM1* and *GSTT1* gene deletions is increased in patients with asthma with concurrent atopy.^{55, 56} In a limited number of cohorts, *GSTM1* and *GSTT1* deficiency increased the risk for asthma, asthma-related symptoms and low lung function during childhood in combination with in utero and/or current passive smoking exposure.^{10, 11, 57} Protective effects of antioxidant supplementation on the lung function of children with asthma exposed to high ambient ozone were restricted to *GSTM1*-deficient participants.⁵⁸ The discrepancy between our study and previous reports with regard to the role of *GSTM1* and *GSTT1* deletions might partly be related to differences in study population, sample size, study design or inhalant exposures. Most importantly, we focused on adult incident asthma whereas the evidence for an association between asthma and *GSTM1* or *GSTT1* was most consistently found in children. Unfortunately, our sample size was insufficient to additionally stratify the results by atopy or exposure to environmental inhalants including ETS.

The strength of the present study is its prospective design which allowed us to investigate the long-term effects of BHR in the general population. The large sample size of the cohort and its detailed characterisation made it possible to investigate the interaction between BHR and GST genotypes on the incidence of adult onset asthma. In addition, it was possible to refine the analysis after exclusion of participants who might have had asthma symptoms at baseline without the formal diagnosis of asthma. Nevertheless, the number of new asthma cases available to estimate the effect modification of baseline BHR by the *GSTP1* genotype was limited. Independent studies are therefore needed to confirm this novel finding.

The definition of asthma in the present study relied solely on the self-report of asthma phenotypes. Asthma status may therefore be subject to misclassification.^{59, 60} The unknown degree of population stratification is another limitation, as no panel of anonymous markers was tested to assay the population admixture of the Swiss general population. However, stratification of the associations by study centre, language region and nationality did not materially alter the main findings, suggesting only a minor influence of population stratification at best. We cannot exclude participation bias. Participants at baseline were less likely to be of intermediate age or of Swiss nationality, but were more likely to be former smokers and to report asthma or wheezing than non-participants.^{18, 19} Unlike participation at baseline, patients with asthma were less likely to participate at follow-up.^{3, 19} Among the non-participants at the follow-up examination there were slightly more men, smokers, subjects with low educational background, subjects with occupational exposure to fumes, gas and dust, and with respiratory symptoms. No difference was noted for atopy and BHR between participants and non-participants at follow-up. Subjects with low lung function—a risk factor for BHR⁶¹—were less likely to undergo methacholine challenge,³ but we had previously presented results from the SAPALDIA cohort which showed that, in contrast to previous evidence,¹⁴ *GSTP1* was not associated with lung function in this adult sample from the general population.¹² In the absence of genotype information on non-participants at baseline and follow-up, we cannot analyse whether we failed to include subjects with unique genotype/phenotype combinations. Even though it is unlikely that

genotype status influenced participation, this possible source of bias also points to the need for independent studies to confirm our result.

In conclusion, we present evidence that the *GSTP1* Ile/Ile genotype may be a strong and prevalent risk factor for the progression of silent BHR to asthma in the general population. If confirmed by additional studies, the results are consistent with the hypothesis that genetic variation in the local metabolism of inhalant-derived chemicals and/or free radicals plays a relevant role in the progression from BHR to asthma.

Acknowledgements: The study could not have been done without the help of the study participants, technical and administrative support, the medical teams and field workers at the local study sites as well as the entire SAPALDIA Team. The authors also thank Esther Glaus for extracting the DNA and Dr med Oliver Senn for genotyping.

Funding: This research has been supported by the Swiss National Science Foundation (grants no 4026-28099, 3347CO-108796, 3247BO-104283, 3247BO-104288, 3247BO-104284, 32-65896.01, 32-59302.99, 32-52720.97, 32-4253.94), the Federal Office for Forest, Environment and Landscape, the Federal Office of Public Health, the Federal Office of Roads and Transport, the canton's government of Aargau, Basel-Stadt, Basel-Land, Geneva, Luzern, Ticino, Zurich, the Swiss Lung League, the canton's Lung League of Basel Stadt/Basel Landschaft, Geneva, Ticino and Zurich and Freiwillige Akademische Gesellschaft, Basel.

Competing interests: None.

Ethics approval: Ethical approval for the study was given by the central ethics committee of the Swiss Academy of Medical Sciences and the Cantonal ethics committees for each of the eight examination areas.
