Pulmonary sequestration
A report of an unusual case and a review of the literature

ARY BLESOVSKY

From the Brompton Hospital, London, S.W.3

A case of extralobar sequestration with findings indicating a pulmonary origin is reported. The literature has been reviewed and evidence presented that intra- and extralobar sequestration are variants of the same abnormality and that the systemic artery is an associated anomaly. From the evidence available at present the pathogenesis of this anomaly is best explained as an abnormality of bronchial and foregut budding resulting from failure of normal embryonic organizer control.

Pulmonary sequestration has become a well-recognized clinical entity since the detailed description of intralobar sequestration by Pryce (Pryce, 1946; Pryce, Sellors, and Blair, 1947). The pathogenesis of, and the relationship between, intra- and extralobar sequestration remain a matter of controversy.

A case of extralobar sequestration is reported because the unusual anatomical features indicated that the lesion had a pulmonary origin.

CASE REPORT

A 42-year-old European woman presented with sudden onset of shortness of breath and pain in the left chest. On investigation she had a haemorrhagic pleural effusion (Fig. 1). No evidence of malignancy was found on microscopic examination of the effusion, at bronchoscopy or at thoracotomy. Before the thoracotomy the effusion was replaced by air and radiography showed a large extrapulmonary mass (Fig. 2).

At thoracotomy the findings were:

1. A large basal pleural pocket was lined by a thick fibrous membrane.

2. The lung had been displaced superiorly by the effusion. Projecting into the space below the level of the lung was a cyst 8 cm. in diameter. The cyst was filled with blood clots that protruded into the pleural pocket through a 2·5 cm. hole in the cyst (Fig. 3).

3. The medial surface of the cyst was against the pericardium posterior to the phrenic nerve.

4. Arising from the upper pole of the cyst was a pedicle containing two patent vessels, one a branch of the pulmonary artery arising outside the pericardium, the other a vein which entered the pericardium to join the superior pulmonary vein (Fig. 3). The cyst did not have a systemic blood supply.

5. The oblique fissure of the lung was very poorly defined and shallow. There was a deep cleft in the upper lobe dividing it into two parts connected by a posterior bridge of lung (Fig. 4).

The membrane was stripped from the lung, chest wall, and diaphragm; the cyst separated with ease from the pericardium and was removed after division of the pedicle. The pedicle was dissected proximally, and the two vessels were ligated and divided at the parent vessels.

The post-operative course was uneventful. A bronchogram was performed before the patient was discharged from hospital (Fig. 5). All segments were present with the anterior segmental bronchus arising from the apical segmental bronchus.

PATHOLOGY The specimen consisted of pleura thickened by organized blood clot and an opened cyst 8 cm. in diameter. The cyst was thin-walled except at one pole where there was an irregular thickening. Microscopically the wall of the cyst showed bronchial structures, ciliated epithelium, cartilage and mucous glands. Muscle was scanty. There were a few areas with rudimentary bronchiolar and alveolar structures. The pedicle contained no bronchial tissue but a venous channel and an elastic pulmonary artery.

DISCUSSION

The deep cleft in the upper lobe together with a pulmonary blood supply to this example of extralobar sequestration indicated that the lesion arose in the lung and was not an accessory 'lung' but a detached segment or subsegment of the lung. The fact that the bronchogram showed no segmental bronchial deficiency does not invalidate this conclusion (Flint, 1906). Because of these findings the literature was reviewed (1) for further evidence of a pulmonary origin for extralobar sequestration; (2) to study the relationship between intra- and

Pulmonary sequestration

trations represent a persistence of accessory bronchial buds which develop during subdivision of the primitive bronchi. These supernumerary buds are usually reabsorbed by the lung and disappear. Persistence within the lung results in intralobar sequestration; acquisition of a blood supply when outside the lung results in persistence as an extralobar sequestration.

Abbey Smith (1956) considered intra- and extralobar sequestrations to be unrelated and precluded a pulmonary origin for the latter condition in postulating his theory of origin of the former abnormality.

A case of extralobar sequestration has been described in which the bronchus, though unconnected to the oesophagus, lay in close proximity to it (Boyden, Bill, and Creighton, 1962). Since it is known that extralobar sequestrations can be connected to the oesophagus (Gans and Potts, 1951; St. Raymond, Hardy, and Robbins, 1956), the authors postulated that in their case this connexion had been lost and that their example ‘and other similarly located supernumerary lungs develop from a diverticulum of the oesophagus’. Similar cases arising from gastric diverticula have also been described (Scheidegger, 1936; Louw and Cywes, 1962).

It is possible that extralobar sequestration can develop from diverticula of the gut, but this theory cannot explain the findings in the present case, and a review of the literature is presented with further evidence for a pulmonary origin of extralobar sequestrations.

The finding of two cysts in an 11.7 mm. human artery has been described (Hammar, 1904). The intralobar cyst was in the apico-posterior segment of the left upper lobe; the extralobar cyst was in the pleural space adjacent to this segment. The shape of the second cyst suggested that it had had a connexion with the lung. The author considered that the cysts had arisen by being nipped off the developing bronchial tree.

The development of the present case is traceable from two similar cases. In the first (Warner, Britt, and Riley, 1958), the sequestration was lying within a wedge-shaped cleft in the left upper lobe; it was entirely free of the surrounding lung and was thought to conform to the anterior segment. Its attachment was a pedicle of fibrous tissue containing its blood supply, which consisted of a branch of the pulmonary artery, a bronchial artery, and a vein running to the left innominate vein. In the second (Baar and d’Abreu, 1949), the sequestration was in the upper part of the left

extralobar sequestration; and (3) to assess the role of the systemic arterial supply in this condition.

ORIGIN OF EXTRALOBAR SEQUESTRATION Bolck (1950), describing a case of combined intra- and extralobar sequestration, considered that sequestration; acquisition of a blood supply when outside the lung results in persistence as an extralobar sequestration.

Abbey Smith (1956) considered intra- and extralobar sequestrations to be unrelated and precluded a pulmonary origin for the latter condition in postulating his theory of origin of the former abnormality.

pleural space, medial to the left upper lobe outside a
deepl cleft in the upper lobe; the tissue was
supplied by a branch of the pulmonary artery and
drained by a pulmonary vein. The position in the
lower chest of the present case can be explained
by adhesion to the pericardium and descent with
it in later development (Cockayne and Gladstone,
1917).

This orderly sequence of change is also trace-
able from normal lung with a systemic arterial
supply to extralobar sequestrations with and with-
out connexion to the lung (Table) and provides
further evidence that some examples of this
variety of sequestration originate in the lung.

### Relationship between Intra- and Extralobar Sequestration

There is agreement that extralobar sequestration is a congenital anomaly, whereas there is disagreement about the congenital or acquired nature of intralobar sequestration. Many authors consider the condition to be congenital and related to extralobar sequestration (Pryce, 1946; Kergin, 1952; Eaker, Hannon, and French, 1958; Parke, 1962).

The view that intralobar sequestration is a nonentity and the changes those of severe bronchiectasis (Gebauer and Mason, 1959) is not in keep-

ing with the pathology (see below).

Abbey Smith (1956) has been the strongest opponent of a common origin for intra- and extralobar sequestration and has made an analysis of the differences between the two conditions. His hypothesis has been accepted by a number of authors (Gallagher, Lynch, and Christian, 1957; Boyd, 1958; Boyd et al., 1962; LeRoux, 1962; Louw and Cwynes, 1962).

It is not the purpose of this article to discuss
that analysis, as objections to it have been
detailed (Parke, 1962), but the arguments in
favour of the congenital nature of intralobar
sequestration and its direct relationship to ex-
tralobar sequestration will be presented.

1. An increasing number of cases of intralobar
sequestration in young children have been
reported (Cohn and Hopeman, 1955; Warner
et al., 1958; Talalak, 1960; Kaufka and Beco,
1960). In one child operated upon for a left lower
lobe sequestration at the age of 6 years, the lesion
had been demonstrated radiographically within a
few hours of birth (Simopoulos, Rosenblum,

The fact that intralobar sequestration has not
been reported in neonatal post-mortem studies
(Potter, 1961; Boyd, 1953) does not preclude its
being a congenital lesion; the lesion is not a lethal
one and is rarely associated with other anomalies,
so its incidence in post-mortem studies will be
low (extralobar sequestration was found only
once in the 10,000 cases in Potter's study, and
that was a gross abnormality associated with hypo-
plasia of the left lung); it is also a lesion partic-
ularly easy to miss unless the pulmonary ligaments
are dissected for anomalous vessels and the pos-
terior basal areas of the lung are examined.

2. The pathology, though sometimes resembling
bronchiectasis, is variable, as would be expected
from a sequestered portion of lung not under normal growth control; the rarity of communication with the normal bronchi (Lalli, Carlson, and Adams, 1954) is also in contrast to bronchiectasis, where the changes affect normally distributed and communicating bronchi.

(3) It is possible to trace an orderly gradation from intralobar to extralobar sequestration. These pass from a sequestration in a normally shaped lobe (the 'typical' type described in numerous reports), to a sequestration where the shape of the lobe is altered (Pryce, 1946, case II), to sequestrations with incomplete fissures (Weisel, Docksey, and Glicklich, 1955), and to those where the sequestration can be shelled away from the rest of the lobe (Cohn and Hopeman, 1955). Then there are intermediate lesions (Bolck, 1950; Parke, 1962) and combined lesions connected by narrow pedicles (Kergin, 1952; Kafka and Beco, 1960). Finally we find the lesions that lie outside a normal lobe but retain a connexion to the lobe via a bronchus (Barlow, 1965; Abul-Wafa, 1954) (Table).

A similar gradation exists in lesions connected to the oesophagus; extralobar sequestration with a bronchial pouch adjacent to but not connected with the oesophagus (Boyden et al., 1962); extralobar sequestration with an oesophageal diverticulum (Gans and Potts, 1951; St. Raymond et al., 1956); intralobar sequestration with an oesophageal diverticulum (Beskin, 1961; Das, Dodge, and Fawcett, 1959); and a stage intermediate between the last two types (Davidson, 1956) where the cyst was connected to the oesophagus and to the lung (Table).

The role of the systemic blood supply in sequestration. The findings in the present case and in two others quoted above show that a systemic artery is not necessary for the development of a pulmonary sequestration, nor could traction by the vessel have played any part in the development in the present case, the findings indicating that the 'cyst' determined the course of the vessels rather than the other way about. Further arguments against the traction theory (Pryce et al., 1947) have been fully documented (Boyden, 1958).

Abbot Smith (1956) put forward the theory that the primary anomaly was a deficiency in the development of the pulmonary artery, leaving the most distal part of the lung, the posterior basal segment, unsupplied by a pulmonary artery. This part retains its primitive systemic supply, and the
lobar sequestration but even between extralobar sequestration situated in the upper and lower parts of the pleural cavity. From a review of the literature it is evident that this is unjustified; just as other congenital abnormalities have a spectrum of anatomically different but related lesions (e.g., tracheo-oesophageal fistula; Fallot's tetralogy; endocardial cushion defect), pulmonary sequestration is represented by a wide variety of lesions with gradation from one end of the spectrum to the other. Though less common with extralobar sequestration, associated anomalies may be present with both types of sequestration. Sometimes the lesion is so complex that the changes cannot be explained by currently accepted theories of origin. The importance of the anomalous arterial supply has been over-emphasized; sequestration can be present without such a vessel, and normal lung can be supplied by a systemic artery.

Any theory of origin of pulmonary sequestration is unacceptable if intra- and extralobar sequestrations are treated as different conditions and if it does not explain the more complex lesions (Davidson, 1956; Talakal, 1960, case 1; Abbey Smith, 1956, unpublished case). Baar and d'Abreu (1949), in describing five abnormalities of foregut duplication (including two extralobar sequestrations and one epiphrenic diverticulum adherent to a bronchietatic left lower lobe), explained the lesions on the basis of interference with organizer centres leading to persistence of accessory foregut buds. Cole et al. (1951) support this view and point out that a primary role cannot be ascribed to the lung, blood vessels, and diaphragm (or to the oesophagus). On the basis of this theory, interference with embryonic organization could affect all structures in an area, whether lung, blood vessels, oesophagus, pericardium, diaphragm, stomach or liver, and the relationship between the anatomically different anomalies can be explained.

I should like to thank Mr. W. P. Cleland for permission to publish the details of this case.
