Spontaneous pneumothorax in young subjects
A clinical and pathological study

I. LICHTER and J. F. GWYNNE

Departments of Thoracic Surgery and Pathology,
University of Otago Medical School, Dunedin, New Zealand

Spontaneous pneumothorax may complicate lung disease which is clinically or radiologically
apparent in patients suffering from chronic bronchitis, asthma, tuberculosis, bronchiectasis, and,
less commonly, bronchial cancer, silicosis, pulmonary infarction, and other rare disorders.
These patients are usually in the older age group, and the commonest predisposing factor is
chronic bronchitis. Pneumothorax occurring in these diseases is well recognized and needs no
further elaboration.

Spontaneous pneumothorax may also occur in apparently healthy people with no demonstrable
pulmonary lesion. The subjects are often young, usually male, and have been in good health
prior to their first episode. They are often athletic and tend to be of tall, thin physique. A group
of 20 cases which falls into this latter category forms the basis of this study. They were all treated
by wedge resection of apical lung disease. The clinical and histological findings are presented and
the literature is briefly reviewed.

Approximately 120 patients were admitted to the Thoracic Surgical Unit of the Wakari Hospital
with spontaneous pneumothorax between the years 1962 and 1968. Most of these patients had clinical
and radiological evidence of established bilateral pulmonary disease such as bronchitis and emphysema,
bronchiectasis or tuberculosis and have not been included in this study.

Fifty of the patients stimulated particular interest because they gave no antecedent history of
chest disease and they form the basis of this study. More than half of this group responded to therapy by intercostal tube drainage. In six
the air leak persisted despite drainage; 14 patients were readmitted because of recurrent pneumothorax. These 20 patients, two of whom suffered bilateral pneumothoraces, were subjected to thoracotomy and wedge resection. The clinical
and pathological data from this group have been reviewed.

CLINICAL DATA

Relevant clinical findings are summarized in the Table.
The indication for resection was recurrence in
14 patients and persistent leak in six. The pneumothorax was bilateral in two patients. Each lung
was affected with approximately equal frequency.

Predilection for the male sex is noted, only three of the patients being females. Sixteen were between
the age of 16 and 30 (range 16 to 47). Two of the older patients were females.

Measurements of body stature were not recorded but most of the patients tended to be tall and thin. A history of athletic activity was frequent.

OPERATIVE FINDINGS

At operation the characteristic findings were as follows:
At the apex of the lung there was a small area of fibrosis, usually no larger than \(3 \times 2\) cm, sur-
mounted by a thin-walled bullous cyst or cysts. Commonly there were several cysts, and these
measured from about 0.2 cm in diameter to 1 cm or more (Fig. 1). Only occasionally was a small pinhole
leak apparent at the apex of the cyst. In the case of leaks that failed to seal within 48 hours of drainage,
a tear was sometimes found in a large cyst that had been responsible for considerable air leak and failure
to heal. The remainder of the lung appeared normal. Adhesions were uncommon.

PATHOLOGY

The histological material from the specimens in the series has been reviewed and a similar pattern of
abnormalities was observed throughout.

</tbody>
</table>

In each case the portion of lung was disorganized by fibrosis, collapse, and cyst formation, all variable in degree. There was no evidence of adhesions to the chest wall.

**Microscopic findings** Histologically the changes were non-specific. Although common features were present, these varied in prominence from case to case, suggesting that the process was in different stages of progression at the time of presentation.

The changes consisted of emphysema and cyst formation, atelectasis, fibrosis, chronic inflammation, pigment deposition, bronchiolar, alveolar cell, and mesothelial proliferation, bronchial lesions, and vascular changes.

**Emphysema and cyst formation** Emphysema was constant and focally distributed, being compensatory in some areas and destructive in others (Fig. 2). Cysts were usually lined by fibrous tissue (Fig. 3).
but a prominent mesothelial layer was present in some instances (Fig. 4). Cysts were usually subpleural but occasionally were seen in scars.

**Atelectasis** This was a constant feature, being distributed either in linear fashion or in ill-defined circular areas. Atelectatic foci were often invaded by fibrous tissue and were in many instances related to adjacent compensatory emphysema.

**Fibrosis** This process varied in nature and distribution. Dense subpleural scars were common (Fig. 5) but in addition the lung tissue itself was fibrosed with replacement of architecture (Fig. 6). In other areas fibrous tissue caused thickening of alveolar walls, especially in foci of atelectasis.

**Chronic inflammation** Active infiltration of dense scar tissue was seen in some cases but this was not the general rule. When present, the cells consisted mainly of lymphocytes and plasma cells, polymorphs being inconspicuous (Fig. 6). Intra-alveolar macrophages were seen frequently. In case 10 there was florid inflammation with foamy macrophages. This patient had been treated elsewhere by camphor oil instillation.

**Pigment deposition** This was inconstant and, when present, was found in macrophages, both in scar tissue and also lying free in air spaces. Both haemosiderin and carbon were identified (Fig. 7).

FIG. 5. Photomicrograph of vascular subpleural scar with a focus of residual inflammation. H. and E. × 50.

FIG. 6. Photomicrograph of focus of cellular scar tissue with residual inflammation. There is fetalization of an adjacent alveolar lining. H. and E. × 115.
FIG. 7. Photomicrograph of pigmented macrophages in alveolar space. Pigment is also deposited in adjacent fibrous tissue. H. and E. × 256.

FIG. 8. Photomicrograph of small bronchi distended with secretion. There is peribronchial inflammation. H. and E. × 115.
Alveolar cell proliferation This occurred in disorganized scarred areas (Fig. 6). The cellular reaction was considered to be related to nearby scarring and inflammation.

Bronchial lesions When bronchi were found in the biopsies, they were on occasion filled with eosinophilic secretion as though obstructed by scar tissue (Fig. 8). Some showed peribronchial fibrosis and mild inflammation of their walls.

Vascular lesions No specific inflammatory or occlusive lesions were seen but endarteritis obliterans was common.

**DISCUSSION**

AETIOLOGY The special site of the damage in each case suggested the possibility of a tuberculous aetiology, but there was no histological evidence for this in any of the cases.

Localized congenital cystic lung was entertained as a possible explanation but the constant relation of cysts to scar tissue made this difficult to assess.

Post-inhalational damage was excluded by the site and by the absence of any evidence of inhaled material apart from carbon.

Localized trauma to the lung suggested itself in view of the youth of the patients and the history of athletic activity, but there was no real evidence of organizing haematomata. The finding of haemosiderin pigments was inconsistent and insufficient to explain the findings on a basis of haemorrhage.

On histological grounds alone the changes are best explained on a basis of post-inflammatory disorganization, the inflammation being most likely due to non-specific infection. The curious localization of the lesions and their occurrence predominantly in young males are obscure features which suggest some local inherent predisposition.

Many of the previous reports relating to primary spontaneous pneumothorax in young subjects have not included detailed accounts of the histological changes (DuBose, Price, and Guilfoil, 1953; Bernhard, Malcolm, Berry, and Wylie, 1962; Carpathios and Bogedain, 1963; Leading article, 1965; Lynn, 1965; Mills and Baisch, 1965; Levy, 1966; Shields and Oilschlager, 1966).

Most authors have favoured a congenital origin for the cysts or have postulated inflammation and fibrosis with cyst formation. An earlier hypothesis by Brock (1948), that air may leak through an imperfect visceral pleura, has not been reiterated in recent studies, all of which record the presence of bullae.

The hypothesis of the patients is of interest and it has been suggested (Withers, Fishback, Kiehl, and Hannon, 1964) that in tall thin individuals there is a rapid growth rate relative to pulmonary vasculature accounting for relative ischaemia and bleb formation during growth. Killen and Gobbel (1968) describe bleb formation with associated fibrosis and chronic inflammation. They point out that the aetiology is unknown but consider that a congenital fault may be present or that the lesion may be secondary to local stress or degenerative change. Similarly, it was suggested in the British Medical Journal (Leading article, 1968) that the lesion might result from a congenital fault or an inflammatory scar. Hyde (1963) drew attention to the long narrow chest and related this to the development of blebs as a congenital anomaly. The same author (1962) had noted the fact that the patients were 20-30 lb (9-13 kg) underweight. Aust (1961) presumed that the blebs were congenital in nature. Thomas (1959) divided his cases into those with congenital cysts and those with acquired blebs or bullae. He indicated that loss of elasticity, fibrosis, and adhesions resulted from pulmonary vascular insufficiency, causing bleb formation.

None of the above authors has incriminated tuberculosis in the aetiology of primary pneumothorax, and this disease was not in evidence in any of our cases.

INCIDENCE The true incidence of apical lung cysts in the population is not known, recognition depending on the complication of rupture. Radiological study prior to the development of pneumothorax is usually negative (Baronofsky et al., 1957; Bernhard et al., 1962; Reid, Stevenson and McSwan, 1963; Leading article, 1968). Our own experience confirms the frequent absence of radiological changes.

According to a leading article in the British Medical Journal (1968) the incidence of the complication of pneumothorax rose from 0-25 per thousand in the 1950s to 0-4 per thousand in the 1960s. This is probably due to better recognition of the condition. Several large series have been reported from military sources and these all stress the importance of the condition in young apparently fit men (Thomas, 1959; Withers et al., 1964; Mills and Baisch, 1965).

The frequency of involvement of both sides at different times in the same patient is worthy of note, and suggests that bullous disease may be present in an intact state on the contralateral side in a significant proportion of patients with apparently unilateral disease. Pneumothorax occurred bilaterally in two of our patients (10%) and this
may rise to a higher figure as our patients are followed up for longer periods. Baronofsky et al. (1957) were so impressed with the bilateral nature of the bullous disease that they performed thoracotomy on both sides in each of their 26 patients. Bullae were found on both sides in all but one of their patients. Details of the pathological findings in their series were not given.

THERAPY  Wedge resection of diseased lung tissue as used in this series of patients reflects the localized apical nature of the disease process which caused the pneumothorax. Failure to understand the focal affection of lung tissue has in the past led to irrational therapy such as pleural cavity obliteration by the instillation of irritating fluids, a procedure liable to fail. When leakage persists for longer than 48 hours, or when the pneumothorax recurs after simple intercostal tube drainage, thoracotomy seems to be the only logical approach to permanent cure. So far, in our series, the results have been good with no recurrences. Baronofsky et al. (1957) recommended resection while Withers et al. (1964) found that the technique compared favourably with other methods. Reid et al. (1963) reported similarly when they compared the results of intercostal tube drainage, kaolin pleurodesing agent, and segmental resection.

CONCLUSIONS

1. A series of 20 patients with recurrent or persistent spontaneous pneumothorax is presented from the clinical and pathological standpoints. All the patients were treated by wedge resection of diseased lung tissue.
2. The pathological features have been reviewed and an attempt has been made to explain the aetiology.
3. The histological lesions are non-specific but suggest post-inflammatory fibrosis and cyst formation. An underlying congenital abnormality related to the anatomy of the thorax in tall thin athletic individuals appears to be an attractive hypothesis. Defects in blood supply and aeration in these circumstances may be important factors.
4. Treatment by wedge resection seems to be a rational approach to the underlying pathology.

We wish to thank the staff of the Photographic Department, University of Otago Medical School, for the photomicrographs, and Mr. D. Tingle for technical assistance. Mrs. D. Schmelz typed the manuscript.
