Honey, M., Pearson, M. C., and Pattinson, J. N. (1976). Thorax, 31, 190-196. A unique pulmonary venous abnormality: with associated pulmonary arterial anomaly and arteriovenous malformation. A man aged 29 was first seen at the age of 11, when he was found to have a congenital anomaly of the pulmonary veins which follow an abnormal course to the hilum. On the left side, two large veins descend peripherally before turning medially towards the left atrium; on the right, several smaller veins follow a similar circuitous route from the periphery, before uniting into two main veins which enter the left atrium. The proximal pulmonary arteries are normal in their pattern of branching and distribution but are dilated and tortuous and taper abruptly: the left lower lobe artery is abnormally large almost down to the diaphragm. There is also a systemic arterio/pulmonary venous fistula. There is no haemodynamic disturbance, but gas transfer is slightly impaired, and there is slight arterial desaturation.

This congenital anomaly is unique. Reported cases described as having pulmonary venous varices are a heterogeneous group, but one patient described as such shows resemblances to our case.

The patient reported here has a hitherto undescribed pulmonary venous abnormality, in which all the major pulmonary veins follow a very abnormal intrapulmonary course but drain normally into the left atrium. This was associated with abnormal pulmonary arteries and a systemic arterio/pulmonary venous malformation in the right lung, arising from the descending aorta.

CASE REPORT

The patient, now 29 years old, was first seen as a boy of 11 in 1956 after a pulmonary vascular abnormality had been recognized at the local chest clinic following mass radiography at school. He was symptomless. A continuous murmur was heard below the right clavicle, but there were no other abnormal physical signs. After investigation he remained under observation as an outpatient for six years. He was re-examined at the age of 25, when no change was found. In 1972 he was refused life assurance and was then re-admitted for further investigation. He still has no symptoms of cardiovascular or respiratory disease but has recently developed migraine associated with transient visual field defect, aphasia, and hemianesthesia.

On examination in 1973 there was no cyanosis nor clubbing. The arterial pulse was normal and regular, and the blood pressure 150/90 mmHg. The venous pressure and pulse were normal. There was still a quiet continuous murmur heard in the second right intercostal space and below the right clavicle. The heart was not enlarged; the heart sounds were normal, and there were no other murmurs. The lungs were clinically normal.

The electrocardiogram showed borderline voltage changes of left ventricular hypertrophy but was otherwise normal. The chest radiograph is described below and illustrated (Fig. 1).

Cardiac catheterization (Table I) showed normal intracardiac pressures. There was no detectable left-to-right shunt, but arterial blood gas analysis showed a slightly reduced oxygen tension. The pulmonary arteriogram and aortogram are described below. Respiratory function tests (Table II) showed no significant ventilatory abnormality, but gas transfer was slightly reduced.
A unique pulmonary venous abnormality

RADIOLOGICAL OBSERVATIONS

The 1956 chest radiograph shows a normal heart size and cardiac contour. The right hilar vessels are prominent, but peripherally in the right lung the vessels are normal in size. On the left side the upper lobe vessels appear enlarged, and a large artery is visible behind the heart. Two abnormal vessels, presumably venous, pass vertically downwards before making an abrupt turn medially towards the heart. A previous film in 1947 had shown slight cardiac enlargement, and the abnormal vascular pattern could be recognized in retrospect. Serial chest radiographs between 1956 and 1973 show no significant change though the abnormal vessels are more clearly seen (Fig. 1).

Pulmonary angiograms were obtained in 1956 by peripheral venous injection, and in 1973 by selective injection into the main pulmonary trunk. These show the proximal pulmonary arteries to be tortuous and enlarged but normal in anatomical distribution. With the exception of the left lower lobe artery, the arterial calibre decreases suddenly at the subsegmental level; the left lower lobe artery remains large until just above the diaphragm where it divides into several small branches (Fig. 2).

The pulmonary veins are grossly abnormal (Fig. 3). On the left side, middle and lower veins course vertically downwards peripherally before turning sharply inwards towards the heart; an

upper vein descends more medially to join the middle vein. On the right side, more numerous veins in the middle and lower zones follow a similar course, descending before turning medially or medially and upwards; these unite to form lower and middle pulmonary veins, the latter then joining the vein from the upper lobe. All the pulmonary veins can be seen to enter the left atrium.

The aortogram in 1973 shows an abnormal systemic artery (Fig. 4a) which had also been noted on the late films of the venous angiogram in 1956. This arises from the descending aorta, is similar in position to but larger than a bronchial artery, and passes to the right upper lobe. A tortuous vessel resembling a pulmonary venous varix fills from it (Fig. 4b), though the angiographic sequence is not sufficiently long to determine its final drainage site. These vessels are partly responsible for the abnormality of the vascular pattern above the right hilum on the plain films.

Anteroposterior and left lateral tomograms show that the abnormal vessels lie within the lung substance and not on the pleural surface or in the fissures. They also show calcification in the wall of the draining vein of the systemic arterio/pulmonary venous malformation (Fig. 5).

**DISCUSSION**

This patient has an abnormality of the pulmonary veins unlike any other we have found in the literature. Normal pulmonary veins take a direct course from the periphery to the hilum of the lung. In our case, abnormal pulmonary veins descend towards the bases before turning medially or medially and upwards: on the left side, there are three major vessels, the upper and middle of which unite before entering the left atrium; on the right side, there are multiple abnormal veins, dilated, elongated, and sinuous, but generally not tortuous, which join to constitute middle and lower veins, the former then joining a relatively normal upper pulmonary vein. In addition, the proximal pulmonary arteries are abnormal in appearance, being dilated and tortuous, and tapering abruptly, and the left lower lobe artery is very large, though the

be present. In the absence of pulmonary hypertension they suggest a structural defect of the vessel wall. Finally, there is a systemic arterio-pulmonary venous anomaly in the right upper lobe. Abnormal pulmonary veins on the left side and the vascular anomaly above the right hilum were apparent on the earliest radiograph taken when the patient was only 3 years old. Though all the radiological changes have become more obvious as the patient has grown, there can be no doubt that the pulmonary arterial, pulmonary venous, and arteriovenous anomalies have all been present from birth.

Pulmonary venous varices have been reported by Hipona and Jamshidi (1967), Rizk, Melhem, and Dagher (1970), Brocard, Vannier, and Gal-louedec (1970), and Bartram and Strickland (1971), and these authors have reviewed a number of similar malformations recorded in the literature. Further cases have been reported more recently by Papamichael et al. (1972), Castell6 Pérez Gómez, and Marazuela (1972), Beamish (1972), Perrott and Shin (1974), and Davia et al. (1974) These varices vary greatly: they are usually dilated, elongated, and more or less tortuous proximal pulmonary veins, draining a single lobe or segment but following an essentially normal course; the peripheral ramifications are normal. The dilatation may be localized, forming a sac, or may extend along the length of the vein. The other pulmonary veins are normal, as also are the pulmonary arteries. In a few cases, the varices are associated with acquired or congenital heart disease. Many of these present with smooth rounded or lobulated lesions seen on the plain chest radiograph which may resemble tumour or pulmonary arteriovenous fistula; these may be single or multiple but show no resemblance to the venous abnormality in this case. In other cases, there is a single dilated, tortuous vein (Mouquin et al., 1951; Kozuka and Nosaki, 1968). In the first case of Brocard et al. (1970), the dilated right lower pulmonary vein descended vertically from the upper part of the lung, turning medially through a right-angle close to the diaphragm; the upper vein was dilated and followed a corkscrew-like course, but its direction was generally normal; both veins entered the left atrium. Bronchography suggested that the right lung was unilobar. In their third case, a large left pulmonary vein which appeared to drain the entire lung descended vertically, turning medially and then upwards to enter the left atrium. In their second case, also with a hypoplastic right lung, an anomalous right pulmonary vein entered the inferior vena cava, and

course and distribution of the vessels is normal. These changes resemble those seen in pulmonary arterial hypertension which has been shown not to
a second vein draining the right lung was said to follow an abnormal course to the left atrium but is not clearly shown in their illustration. On the basis of their experience, Brocard et al. (1970) suggest that pulmonary varices of the type they have encountered are usually part of a complex malformation, involving also pulmonary arteries and bronchi, and as such are related to the scimitar syndrome. Though there are points of similarity, none of these cases closely resembles the one we have described.

On the other hand, Kaindl, Kotscher, and Lobenwein (1971) have described a patient in whom the pulmonary venous abnormality is more like that seen in our patient. In their case 4, the right lung veins were dilated and unusually long, and followed a sinuous course from periphery to hilum with siphon-like loops turning back on themselves and few branches. The central pulmonary veins were normal and entered the left atrium. The pulmonary venous anatomy on the left side is not well shown on their illustrations. As in our case, the proximal pulmonary arteries on both sides were dilated and tortuous.

Our view is that the pulmonary venous abnormality in our case represents a congenital anomaly of the course and distribution of the pulmonary veins. The pulmonary venous system evolves from a primitive plexus on the ventral aspect of the lung bud of the embryo. We can offer no explanation of the factors determining the pattern and course of the lobar and segmental veins either in the normal lung or in our case. At an early stage in development there are anastomoses between the pulmonary plexus and the posterior and common cardinal veins, which may persist and lead to partial anomalous pulmonary venous drainage to systemic veins on either side. In our case, though the development of the normal direct pathway to the hilum of the lung has been inhibited by some unknown mechanism, the alternative and circuitous route reaches a normal destination.

This curious pulmonary venous anomaly has not resulted in any haemodynamic disturbance and indeed none would be expected. It seems likely that the slightly reduced arterial oxygen tension and saturation results from a ventilation/perfusion imbalance. Though distribution of ventilation has not been measured, there is no significant disturbance of overall pulmonary ventilation, and it is probable that the distortion of the orderly anatomical pattern of pulmonary venous drainage has resulted in an abnormal distribution of pulmonary perfusion. The resulting impairment of gas exchange is, however, slight, unaccompanied by any subjective disability and unlikely to affect prognosis adversely. Though haemorrhage from pulmonary varices is reported, this has occurred in those patients in whom the varix is localized and sac-like, and there seems to be no reason to anticipate this complication in our case. Possibly, however, reduced velocity of blood flow and the late development of degenerative changes in the vein wall might predispose to pulmonary venous thrombosis. It is unlikely that the development of migraine albeit with severe prodromal symptoms is related in any way to the pulmonary venous anomaly, though a congenital cerebral vascular lesion has not been excluded.
