Beltrami, V. and Gidarò, G. (1976). Thorax, 31, 350-353. Resection and reconstruction of the sternum: case report. The case history of a 67-year-old man who underwent a subtotal sternectomy for a tumour of the manubrium and left clavicle is reported. Histological examination revealed a highly undifferentiated metastatic carcinoma: the original tumour was not discovered but the patient was in good condition 10 months after operation. Adequate replacement and stabilization of the chest wall was obtained with autotransplantation of the tibia and muscle flaps.

Sternal tumours are relatively uncommon and their malignancy is usually high. They are often metastatic from neoplasms of the lung, breast, kidney or thyroid.

Partial or total resection of the sternum for malignant tumours has been performed up to now in no more than 60 cases. Various methods of reconstruction have been used, for example, mobilization of peripheral tissues, autogenous grafts, and prosthetic devices.

CASE REPORT

Our patient was a 67-year-old man. In the previous two months he had noticed a small mass in the sternal end of the clavicle; this was hard in consistency and painless and had rapidly increased to reach the size of an egg (Fig. 1). Physical examination revealed that the neoplasm was attached to the clavicle and manubrium sterni. The sedimentation rate was high (KI=81).

Radiographs showed an osteolytic lesion of the sternal end of the left clavicle and of the manubrium (Fig. 2). Bronchography, barium study, mesenteric angiograms, urography, and isotopic study of the liver and thyroid were non-contributory.

Resection of the manubrium, the inner third of the left clavicle, and the sternal end of both the first two ribs was performed.

Two split tibial grafts, each 8 cm long, were sutured with steel wire to the resected ends of the first and second ribs in order to close the defect in the anterior chest wall (Fig. 3). The pectoralis muscles and subcutaneous tissues were drawn together in the midline to cover the autogenous grafts. A drainage tube was placed in the subcutaneous space and the skin was closed.

The patient had an uneventful postoperative course without paradoxical respiration (Fig. 4).

Histological examination revealed a highly undifferentiated metastatic carcinoma of uncertain origin. Further search for the primary tumour was unsuccessful. The patient is well 10 months after the operation.

DISCUSSION

From 10 to 15% of neoplasms of the thoracic skeleton are located in the sternum. Benign and primary malignant tumours are unusual; metastases from the thyroid, breast, kidney, and lungs form the majority in most reported series.

A palpable mass is the commonest sign; bone pain is present in 10% of cases. Diagnosis is not easy; metastases in bones may be either osteoplastic or oestolytic, and since primary malignant tumours can behave in the same way, radiographs cannot offer a certain diagnosis. On the other hand, pathological fractures—which may be the first indication of bone metastasis—are unusual in the sternum.

Resection of the sternum, total or partial, poses problems. Chest wall stability, protection of the thoracic organs, and prevention of paradoxical respiration are required. Different methods have been employed to solve these problems: satisfactory results have been obtained both with autogenous grafts and with prosthetic devices (Table). In our patient, split tibial grafts and flaps of muscle were used with a good result.

Cotton (1949) and Bisgard et al. (1949) reported cases of bone metastases present in 10% of cases. Diagnosis is not easy; metastases in bones may be either osteoplastic or oestolytic, and since primary malignant tumours can behave in the same way, radiographs cannot offer a certain diagnosis. On the other hand, pathological fractures—which may be the first indication of bone metastasis—are unusual in the sternum.

Resection of the sternum, total or partial, poses problems. Chest wall stability, protection of the thoracic organs, and prevention of paradoxical respiration are required. Different methods have been employed to solve these problems: satisfactory results have been obtained both with autogenous grafts and with prosthetic devices (Table). In our patient, split tibial grafts and flaps of muscle were used with a good result.
