Chylothorax: diagnosis by lipoprotein electrophoresis of serum and pleural fluid. This report describes a 31-year-old woman who underwent a technically difficult left pneumonectomy for tuberculosis and developed thereafter a large left pleural effusion which was milky in colour. A traumatic chylothorax was suspected, and the diagnosis was confirmed by simultaneous fasting pleural and serum lipid studies and lipoprotein electrophoresis. The latter study was especially helpful in confirming the chylous nature of the fluid in that it revealed a marked chylomicron band at the origin; this was not present in the patient's serum nor in the pleural fluid of five patients with other disease states studied as controls.

The diagnosis of chylothorax is usually suspected when milky fluid is removed at thoracentesis. Another entity, however, the pseudo-chylous pleural effusion, may be indistinguishable in appearance. It consists of a cholesterol-rich fluid with low or absent triglycerides which results from chronic pleural infection or inflammation (Roy *et al.*, 1967). The presence of fat globules stained by Sudan dyes on microscopic examinations of milky pleural fluid was thought to confirm the diagnosis of chylothorax. However, this has been shown to be incorrect by Denborough and Nestel (1964). It appears, therefore, that only chemical analysis of the precise lipid composition of milky effusions can confirm their nature as truly chylous.

Chylothorax may arise spontaneously and without apparent cause, may occur as a result of malignancies of the lung and mediastinum, or may follow blunt or penetrating chest trauma (Bessone *et al.*, 1971; MacFarlane and Holman, 1972). Chylous pleural effusions may also result from various thoracic surgical procedures. Since the thoracic duct crosses to the left of the spine between the fifth and seventh thoracic vertebrae, it is especially vulnerable to traumatic injuries during operation on the left hemithorax near the hilum, including procedures on the heart and great vessels, and resections of the oesophagus and left lung (Goorwitch, 1955; Selle *et al.*, 1973). This report

describes a young patient who developed a milky left pleural effusion after a difficult left pneumonectomy for tuberculosis, and in whom simultaneous fasting serum and pleural fluid lipid and lipoprotein electrophoretic studies proved of value in confirming the chylous nature of the fluid.

Case report

A 31-year-old black woman was first discovered to have active tuberculosis of the left upper lobe, lingula, and left lower lobe in February 1969. She was at that time admitted to the Tuberculosis Section of the Division of Pulmonary Medicine at this institution for treatment. After a brief spell in hospital she was discharged on isoniazid and ethambutol, but failed to take the tablets regularly. Her sputum again became positive with radiographic progression and she was readmitted in September 1969. After a period of sputum conversion accomplished with rifampicin and pyrazinamide, her sputum became positive again and remained positive thereafter. A left pneumonectomy was therefore carried out on 17 October 1973. It was a technically difficult operation requiring an extrapleural dissection over the upper lobe and lingula. No drainage tube was used postoperatively.

By the tenth postoperative day, although the

patient was free of symptoms, fluid was seen to be oozing from the surgical incision. Thoracentesis revealed milky fluid, and a traumatic postoperative chylothorax was diagnosed. The fluid rapidly reaccumulated, and it was considered to be important to confirm the diagnosis as simply and expeditiously as possible.

To attempt a biochemical diagnosis, pleural fluid and serum were simultaneously examined with the patient in the fasting state for (1) cholesterol, (2) triglycerides, and (3) lipoproteins by electrophoresis (Abell *et al.*, 1952; Fredrickson and Lees, 1966; Van Handel and Zilvermit, 1957). The results of the cholesterol and triglyceride determinations are noted below:

	Serum	Pleural fluid
Cholesterol	175 mg/100 ml (4.5 mmol/l)	96 mg/100 ml (2.5 mmol/l)
Triglycerides	75 mg/100 ml (0.64 mmol/l)	538 mg/100 ml (6.1 mmol/l)

The Figure shows the simultaneously determined lipoprotein electrophoresis patterns in serum and pleural fluid.

These studies revealed that the serum was clear and that both its lipid and lipoprotein electrophoretic patterns were normal. The pleural fluid, however, was lactescent and contained large concentrations of triglycerides. The lipoprotein electrophoretic pattern of the pleural fluid showed a marked chylomicron band at the origin, indicating the chylous nature of the pleural fluid.

In an attempt to ascertain the specificity of these lipid studies for chylous effusions, pleural fluid was obtained for study from five other patients with non-milky pleural effusions. Three had tuberculous effusions and two had bacterial empyemas. The mean pleural fluid cholesterol was 72 mg/100 ml (1.9 mmol/l) in these five patients (range 54–83 mg/100 ml (1.4–2.1 mmol/l)). Their mean triglyceride concentration was 19 mg/100 ml (0.2 mmol/l) (range 10–27 mg/100 ml (0.1–0.3 mmol/l)). Finally, on their lipoprotein electrophoresis, only a faint band at the level of beta or pre-beta lipoprotein was seen without any chylomicron band at the origin.

Fortunately, in our patient chyle did not accumulate after the second thoracentesis. The patient steadily improved and was discharged. Six months after discharge her sputum was negative and no evidence of fluid was noted on the chest radiograph. At present, three years after surgery, she is entirely well.

Figure Electrophoretic pattern of serum (left) and pleural fluid (right) lipids. Serum pattern is normal. The pleural fluid reveals a marked chylomicron band.

Comments

This case illustrates a fortunately rare complication of resectional lung surgery, that is, chylothorax after a difficult left pneumonectomy. The clinical course of our patient is typical of chylothorax following surgical trauma. The rapidity of its development is related to the size of the thoracic duct injury and the dietary intake of fats. Surgical trauma to the thoracic duct usually results in the development of chylothorax on the seventh to 14th postoperative day, while chylothorax develops about six weeks after blunt chest trauma. There is, however, a wide range of times of onset, depending upon the severity of the trauma. It is now believed that patients with postoperative chylothorax will heal with conservative treatment within three to four weeks, that is, without surgical reoperation and repair of the thoracic duct (Randolph and Gross, 1957; Schmidt, 1959). Bessone *et al.* (1971) recommend that 'all patients with congenital, postoperative, or traumatic chylothorax, in whom immediate thoracotomy for the control of an associated lesion is not required, should be managed by initially conservative methods'. Conservative management includes adequate pleural drainage and a
