ABSTRACT Evidence of a clotted false lumen in patients with acute aortic dissection has been considered to be a primary indication for medical rather than surgical therapy. A review of recent publications shows that 14 of 15 such patients survived with medical management. We present three patients who had radiographic, surgical, or necropsy evidence of acute aortic dissection with a clotted false lumen, who suffered further dissection in spite of adequate medical therapy. Our experience indicates that this condition is not as stable as it has been considered in the past. Consequently, we believe that great caution should be exercised in the application of medical therapy and in the follow-up of patients who demonstrate evidence of a clotted false lumen in an acute aortic dissection. Surgical treatment is indicated at the earliest sign of clinical or radiographic deterioration during medical therapy.

Selection of the appropriate therapy for acute aortic dissections has remained a controversial and difficult problem. Although it was once thought that all such dissections should be surgically treated, Wheat et al in 1965, demonstrated that medical therapy could be successful in appropriately selected patients.1 Subsequently, several reports confirmed these findings,2-4 and the criteria for separating patients into medical and surgical treatment groups have become more clearly defined.4-5 The suggested presence of a clotted false lumen on aortography has been generally accepted as one of the primary indications for medical therapy.2 4-6 In this report we describe three patients in whom the presence of a clotted false lumen was suggested angiographically and for whom medical management was eventually unsuccessful. The clinical course of these cases suggests that the indications for medical therapy of acute aortic dissection with clotted false lumen should be re-examined.

Case reports

CASE 1
A 67-year-old hypertensive white woman was referred to the University of Chicago Hospitals with a 24-hour history of severe back pain. On physical examination the blood pressure was 130/100, the right carotid pulse was diminished, and there were bruits over both carotid arteries, both external iliac arteries, and the abdominal aorta. A chest radiograph demonstrated widening of the mediastinum and a left-sided pleural effusion. Emergency aortography suggested a diagnosis of acute aortic dissection (De Bakey type I) with a clotted false lumen (fig 1).

A thoracocentesis yielded bloody fluid and treatment was started with antihypertensive agents and diuretics. On the second day of treatment the patient had a pulmonary embolus (confirmed by angiography) and an inferior vena caval filter was inserted.

The blood pressure, which was initially very labile, slowly came under control and her condition stabilised. Serial chest radiographs failed to show any alteration in the mediastinum.
Aortic dissection: reappraisal of medical management

On the thirty-third day of treatment the patient experienced another episode of severe back and chest pain followed by dyspnoea and the blood pressure once again became very unstable. A chest radiograph showed no appreciable change in the appearance of the aorta compared with previous films (fig 2). Shortly afterwards the patient became hypotensive and had a cardiac arrest from which she could not be resuscitated.

Postmortem examination revealed a dissection of the thoracoabdominal aorta. The false lumen contained multiple clots in varying stages of organisation (fig 3).

CASE 2
A severely hypertensive 47-year-old black man was admitted to The University of Chicago Hospitals with back pain. Physical examination was unremarkable. A chest radiograph demonstrated a widened aortic shadow (fig 4). Emergency aortography confirmed the clinical diagnosis of acute aortic dissection (De Bakey type III) with a clotted false lumen (fig 5). The patient responded well to treatment with antihypertensives and diuretics and was discharged after 20 days in hospital.

Nine months later he was readmitted with recurrent symptoms. On examination the left leg pulses were markedly diminished. The chest radiograph (fig 4) and aortogram (fig 6) demonstrated an increase in size of the aortic knuckle and expansion of the previously clotted false lumen.

The patient underwent successful surgical repair of the aortic dissection. Intraoperative exploration verified the presence of a medial dissection of the thoracic aorta with thrombus in the false lumen. The postoperative course was uncomplicated and the patient was discharged in good condition. He continues well 18 months after the procedure.

CASE 3
A 74-year-old white man was admitted to Long Beach Memorial Hospital with a two-hour history of severe back pain. There had been no significant previous illnesses. The patient's blood pressure was 165/100 but otherwise physical examination was unremarkable. A chest radiograph demonstrated an enlarged aortic knuckle (fig 7). An emergency aortogram revealed dissection of the thoracic aorta (De Bakey type III) with a clotted false lumen (fig 8). Antihypertensive
treatment relieved the patient's symptoms and he was discharged after 30 days in hospital.

Three weeks after discharge the patient became hoarse and was readmitted to hospital. A chest radiograph showed considerable enlargement of the aortic arch and descending aorta (fig 7). However, an aortogram again demonstrated a clotted false lumen (fig 8).

Exploration confirmed the findings of the aortogram. The thoracic aorta was replaced with a tubular graft but the patient died suddenly on the eighth day after the operation. A necropsy demonstrated a new dissection originating distal to the graft. The surgical repair was satisfactory.

Discussion

The selection of treatment for patients with acute aortic dissection has been reviewed recently. The suggestion of a clotted false channel on aortography has been considered a primary criterion for medical management. A review of recent publications shows a 93% long-term survival for medically treated patients with angiographic indications of clotted false lumina (table). It is not clear why these patients enjoy apparent protection from expansion or rupture of their dissections. Multiple factors have been postulated among which is the suggestion that the thrombosed
channel provides a buttress against further rupture or extension.

In contrast to the above observations, our three patients with confirmed clotted false lumina failed to respond to medical therapy alone, thus challenging the previously held view on management of such patients. There are several reasons why this discrepancy might exist. First, the angiographic criteria for diagnosis of a clotted false lumen are ill-defined. It is possible that patients with a clotted false lumen who have had a second dissection may not have been diagnosed accurately.

originally. Conversely, patients believed to have clotted false channels who have done well on medical therapy might also have been misdiagnosed. Our present series is unique in that we have surgical or necropsy confirmation or both of the dissection process in all cases.

It is also possible that the selection of patients for medical treatment as previously reported might be biased, giving a false impression of the stability of the clotted false channel in aortic dissection. To our knowledge, there has been no randomised trial of medical versus surgical treatment in these patients.

The cases presented here demonstrate that expansion of the original dissection and new dissection are possible in patients with clotted false lumina despite apparently successful medical therapy. In view of this, we feel that decisions to treat these patients medically should undergo careful scrutiny. This is not to say that medical treatment has no role in the management of these patients. The inclusion of our three patients in the above quoted series still gives a survival rate of 78% for the medically treated group. In all three cases, the subsequent crisis was an extension of the previous dissection, but in addition, in case 3, a new dissection arose distal to the initial site of disease which had been treated surgically.

We have no evidence as yet to suggest that surgical treatment will lead to a better long-term result when a clotted false lumen exists. Indeed in a review of acute aortic dissection over the past 10 years in this institution which we are at present completing, we have uncovered three further patients who had definite evidence of a clotted false lumen. Of these three, one was severely hypotensive on arrival and was treated medically but died 24 hours later of rupture of the descending thoracic aorta. At necropsy there was organised clot in the false lumen of a type 1 dissection. The other two patients had definite angiographic evidence of a clotted false lumen in type 3 dissections and were treated medically. Both survived, one at least six months the other at least six years. The outcome of case 1 and the first case mentioned here could not have been worse had surgery been performed.

We now advise, however, that patients with acute aortic dissection in whom the presence of a clotted false channel is suggested on aortography should no longer be considered prime candidates for continuous medical treatment. After initial stabilisation frequent assessment should be made to provide assurance of successful treatment. Although aortography remains the most useful method of assessing the nature and extent of aortic dissections, the limitations of this technique are apparent. In future, better evaluation may be available through the use of newer non-invasive techniques such as fibrinogen isotope scanning or computerised tomography.

Aggressive investigations of suggestive symptoms in these patients should be undertaken to rule out progression or change in the dissection. When medical therapy appears to be unsuccessful, surgical treatment should be instituted promptly.
Aortic dissection: reappraisal of medical management
