ABSTRACT The results of ligation of a patent ductus arteriosus in 30 premature neonates with a very low birth weight were analysed. The mean gestational age at birth was 27 weeks and the mean weight 811 g. Attempted closure of the ductus with indomethacin in 19 infants failed, though there was temporary closure in nine. Congestive heart failure was present in 29 and respiratory distress in 22 patients. Endotracheal intubation with assisted ventilation was necessary in all cases. The mean age at operation was 13.5 days and ductal ligation was performed in the intensive care unit under local anaesthesia supplemented with pancuronium and pethidine. There were no intraoperative deaths, but five infants died in hospital. There were seven late deaths. Eighteen survivors have been followed for a mean of 26.5 months. Early ligation of a patent ductus arteriosus in premature infants with a very low birth weight improved the cardiorespiratory state. Long term follow up showed good clinical progress in two thirds of the survivors.

Delayed closure of a patent ductus arteriosus in premature neonates may be a factor in causing congestive heart failure and respiratory distress. Medical treatment with indomethacin, a prostaglandin synthetase inhibitor, has been used despite reports of a varying response and the risk of renal insufficiency and gestational bleeding.

It has been our policy to recommend surgical ligation of a patent ductus arteriosus in premature neonates unresponsive to a short trial of medical treatment for cardiac failure or respiratory distress. In central Israel our cardiovascular surgical unit provides a surgical service to four neonatal intensive care units over an area of 3600 square kilometres. To avoid moving these critically ill infants, the operations were performed in the neonatal intensive care units, which were 40-70 km from the surgical unit. This report discusses our experience, including the surgical management and follow up of the survivors.

Patients and methods

Thirty premature neonates (19 of them boys)

 infants. The apnoea bradycardia syndrome was present in 14 patients, who were treated with isoprenaline, atropine, and assisted ventilation, alone or in combination.

The patients were assessed for the presence of a haemodynamically important patent ductus arteriosus by an aggregate diagnostic scheme of first order and second order criteria and additional clinical findings, described by the National Collaborative Study on patent ductus arteriosus in premature infants. Bounding pulses and a hyperdynamic praecordium were present in 29 of the 30 patients; a continuous murmur was present in four, a systolic murmur in 24, and no murmur in two patients. In addition to the ventilatory criteria, these “silent ducts” had positive chest radiographic findings to confirm their haemodynamic importance.

Chest radiographs showed cardiomegaly in 18, pulmonary plethora in 14, and perihilar oedema in 22 patients. Significantly, the early changes of bronchopulmonary dysplasia were present in 10 and a preoperative pneumothorax in two patients. Cardiac catheterisation was done only in the first patient in the study and echocardiography was not performed. Pulmonic stenosis was suspected in one patient and ventricular septal defect in another. Preoperative systemic lesions and complications are detailed in table 1.

After the diagnosis of a haemodynamically significant patent ductus arteriosus was made, a trial of medical therapy was attempted to wean the patient from the respirator. Indomethacin was administered to 19 patients. In the remaining 11 it could not be used because of hypercreatininaemia in 8; pulmonary haemorrhage in one; cephalohaematoma, cholestatic jaundice, renal failure and haemoperitoneum in one; and unavailability in two patients. One patient had both hypercreatininaemia and pulmonary haemorrhage. Respiratory distress did not improve in any of the 19 patients who received indomethacin. Despite temporary ductus closure in nine patients the development of thrombocytopenia in two and hypercreatininaemia in one patient led to the abandonment of indomethacin therapy.

Surgical ligation was performed once medical treatment had failed. At the time of operation the mean age was 17 (range 4–42) days and the mean weight 842 (range 650–1320) g. Only three patients weighed more than 1000 g. The first patient in this series was moved to the operating room for ligation of patent ductus arteriosus, but all other patients were operated on in a partitioned area in the neonatal intensive care unit. All essential personnel were masked and gowned. Sterile gowns, drapes, and instruments brought from the operating theatre were used to maintain a sterile field and avoid contamination. General anaesthesia with nitrous oxide and oxygen was used only in the first patient. All others were operated on under intravenous pethidine, atropine, and pancuronium. Xylocaine 0.5% was infiltrated locally and surgical ligation of the patent ductus arteriosus was performed with 2–0 silk through a left posterolateral fourth interspace thoracotomy. An Ethicon LC-200 medium size haemoclip was used for ductal obliteration in the last patient of the series. All babies had a left chest drain for 12–48 hours.

The size of the ductus did not show any correlation with the preoperative clinical state, gestational age, or the presence or absence of respiratory distress or cardiomegaly. It was as large as the aorta in six cases and two thirds of the aortic diameter in 14, half in five, and one third in five.

**Operative results and complications**

No neonate died as a direct result of anaesthesia or the operative procedure. Two patients died in the first 28 days of life, resulting in a neonatal mortality rate of 6.6%. The hospital mortality was 16.6% (five patients). Seven babies died from two to seven months after operation.

Respiratory failure caused three of the hospital deaths. Preoperative bronchopulmonary dysplasia was noticed in two and pulmonary haemorrhage in the third. A fourth baby died from sepsis and extensive intravascular thrombosis and the fifth from intracranial haemorrhage, renal failure, and sepsis. Sepsis was present before operation in both of these.

Intracranial haemorrhage caused two late deaths. Two other babies succumbed during spells of bradycardia three and a half and six and a half months after operation. The remaining three infants died from respiratory failure. Preoperative bronchopulmonary dysplasia and postoperative sepsis had been present in three of them.

Thus preoperative bronchopulmonary dysplasia unaffected by ductal ligation was a factor in five out of the total 12 deaths. Sepsis due to an immature immune system was an important factor in five of the deaths.

The mean age at operation was 16 days for those who survived and 21 days for those who did not. The mean weight at operation was 835.5 g for the survivors and 835.6 g for those who died. These differences are not statistically significant. The significance of a birth weight of more than 1000 g could not be assessed as there were only three neonates in this group. Associated complications in those who died are shown in table 2.

The complications in the survivors are shown in table 3. Eighteen were followed up for three months to five years (mean 26.5 months). Follow up assessment combined the use of the Amiel Tison first year neurological examination coupled with the Bayley scales of infant development whenever possible. Ophthalmological examination when indicated included fundoscopy and cycloplegic refraction. Free field audiological tests were done when abnormalities were suspected.

Recurrence of patent ductus arteriosus was noticed in two patients. Bronchopulmonary dysplasia was found to continue in six of the survivors. One developed cor pulmonale and the other lobar emphysema. Three infants developed retrolental fibroplasia and two required cryosurgery. Rickets developed in five of them and was corrected with medical treatment. Subglottic stenosis occurred in one patient. Intracranial bleeding led to ventriculitis in one patient, who required a ventriculoperitoneal shunt. Cerebral palsy with psychomotor retardation and pseudotumour cerebri with a convulsive disorder each occurred in one child. Two patients were mentally retarded.

Discussion

The best location for surgical ligation of a patent ductus arteriosus in neonates has been debated in published reports. A proper operating room has been preferred by many, but several centres now prefer to eliminate the problems of transportation to an operating theatre and thus avoid the risks of thermoregulatory instability, loss of intravenous lines, malfunction and accidental discontinuity of monitoring, improper ventilation, possible airway loss, and underhydration or overhydration with fluids. In the neonatal intensive care unit the neonate is already intubated and on a respirator, venous lines and umbilical arterial catheter are in place, and monitors are already connected for heart rate, respiratory rate, body temperature, and arterial pressure. Comparison of the results of these two groups show no advantage of patent ductus arteriosus ligation in the operating theatre. We preferred to minimise the risks in these critically ill babies and adopted the policy of operating in the neonatal intensive care unit.

One of the main advantages is in maintaining normothermia, which is easier in the partitioned area in the NICU than in the operating theatre. All of our patients were maintained at 36–38°C. The isolettes on which they were placed for the operation had temperature control. The ambient temperature of the room was usually 38°C. Heating lamps, warming blankets, and wrapping of the extremities and head with sheet wadding were used. All transfusates and infusates were warmed to body temperature before administration.

There is no unanimous agreement about the ideal anaesthetic management of these neonates. Most anaesthetists prefer to avoid or use sparingly the potent inhalation anaesthetics. Nitrous oxide causes myocardial depression. Despite this, the combination of nitrous oxide with oxygen with or without relaxants and narcotics has been used by many for general anaesthesia. Lipman et al reported a series of 24 patients who had had oxygen, succinylcholine, and local anaesthetics. Robinson and Gregory reported the use of fentanyl and pancuronium combined with oxygen and air, which produced minimal circulatory disturbances. A ketamine, pancuronium, oxygen, and air combination has also been suggested in published reports. We used...
pethidine, atropine, pancuronium, oxygen, air, and local anaesthetic in combination, on the hypothesis that this would cause minimal circulatory disturbance with effective control of pain. Absence of intraoperative bradycardia and hypoxia (checked by continuous TcPo2 monitoring) supported our hypothesis. There was no postoperative complication that could be attributed to anaesthetic management. Optimal oxygenation during operation means maintaining oxygenation within a very narrow range and TcPo2 monitoring provides excellent indication of control. During brief spells of vigorous lung retraction 100% oxygen has to be administered to prevent bradycardia. Though hypoxia is generally more damaging than hyperoxia, Betts et al22 correlated the late development of retrolental fibroplasia with brief periods of hyperoxegenation during general anaesthesia.

Several factors have been evaluated as predictors of patients’ progress and prognosis. Gay et al23 correlated large shunt duration with survival and the late development of bronchopulmonary dysplasia. Clarke et al24 analysed their data and those of nine other series and concluded that in respirator dependent neonates with respiratory distress and patent ductus arteriosus the shorter the large shunt duration the lower the mortality rate. They concluded that a large shunt duration of more than eight days significantly increased the mortality rate. We did not find any correlation of large shunt duration of eight days with survival and the late development of bronchopulmonary dysplasia in our patients. Clarke’s group further observed a correlation of the average FiO2 requirement with the development of bronchopulmonary dysplasia, the FiO2 requirement being appreciably less in patients without dysplasia. We did not notice any such correlation among our survivors.

Early ductal ligation resulted in a shorter period of intubation, in patients weighing less than 1500 g, than was possible in the medical treatment group in the series reported by Mikhail et al.10 Our experience corroborates that. Contrary to their other conclusion, however, early ligation was not found to influence the progress of bronchopulmonary dysplasia if this was already present before operation.23 25 26 Hall et al27 found chronic lung disease, in many cases with cor pulmonale, in six of their 14 long term survivors. Apparently ligation of the patent ductus arteriosus did not reverse or arrest the progress of lung disease in those patients. Brandt and coworkers28 in a later follow up (after one to five years) of 51 survivors found radiographic evidence of bronchopulmonary dysplasia in 17 patients (34%) and no residual sequelae were noticed in only 24 survivors (less than 50%). This perhaps puts the role of surgical intervention in its proper perspective. This is no “miracle cure in babies with marginal hope for a normal life.”29 It does, however, increase the quantity of life in these sick neonates who may not otherwise survive at all.

The role of patent ductus arteriosus ligation differs considerably in premature babies with and without respiratory distress.25 30 In eight out of 30 patients in our study who had no preoperative respiratory distress only two died. One succumbed three and a half months after operation at the age of 128 days owing to a spell of bradycardia. The second died from intracranial haemorrhage and sepsis 38 days after operation. All others had a rapid recovery and left hospital.

The influence of patent ductus arteriosus on pulmonary mechanics, gas exchange, and evolution of bronchopulmonary dysplasia remains undefined. Ductal patency possibly does not decompress a hypertensive pulmonary vascular bed.30 Rudolph and coworkers31 showed low pulmonary and systemic arterial pressures in critically ill premature neonates with respiratory distress. Most of their patients had a dominant left to right shunt, though a mixed shunt was reported in some. Levitsky et al32 noted that even patients with a small shunt that is not necessarily large enough to increase the size of the left atrium will show a decrease in pulmonary compliance. Coran and colleagues33 support the observations of Rudolph’s group. Possibly large left to right shunts continue to cause pulmonary damage after causing left heart failure. Left atrial volume overload raises pulmonary venous and capillary pressures, resulting in alveolar transudation and impaired gas exchange. Aggravated ventilation-perfusion inequality results in reduction of lung compliance. This leads to further decreased oxygenation and impairment of an already stressed left ventricle. Whether ductal interruption may reverse the process at this stage has not yet been determined. In our follow up of 18 long term survivors persistent bronchopulmonary dysplasia was noticed in six, of whom five had it before operation. Apparently surgical ligation neither reversed nor influenced the dysplasia in these babies.
