Absorption of $^{51}$Cr EDTA across the human nasal airway barriers in the presence of topical histamine

Lennart Greiff, Per Wollmer, Ulf Pipkorn,* Carl G A Persson

Abstract

Whether histamine, a mediator that causes exudation, affects the airway absorption of luminal solutes has been examined in a study of eight healthy volunteers. Fluid containing the absorption tracer chromium-51 labelled EDTA was instilled into one nasal cavity for 15 min with a nasal pool-device (total volume 14 ml). The airway absorption of $^{51}$Cr EDTA determined by urinary recovery of radioactivity corresponded to 0.095 (SE 0.023) ml of the instillate in the absence of histamine. When histamine was added to the nasal instillate at a concentration of 2.0 mg/ml, which is known to produce substantial exudation of plasma into the airway lumen, the absorption of $^{51}$Cr EDTA was unchanged (0.093 (0.025) ml of the instillate). Separate experiments excluded the possibility that any swallowed portion of $^{51}$Cr EDTA could have contributed significantly to the amount absorbed. The present data agree with previous observations in guinea pig tracheobronchial airways, where histamine and other exudative agents did not increase the mucosal absorption of solutes from the airway lumen. These data suggest that the potent protein systems of blood plasma can transverse the endothelial-epithelial linings and operate on the surface of the airway mucosa without compromising its integrity as a barrier to luminal material.

Methods

SUBJECTS

Nasal absorption of $^{51}$Cr EDTA was examined in eight healthy male non-smokers aged 22–28 years. The subjects had no known airway disease and the nasal mucosa was normal on inspection. Gastrointestinal absorption of $^{51}$Cr EDTA was examined in a separate group of six healthy male non-smokers aged 25–38 years. No drugs were allowed during the course of the study. Informed consent was obtained from the subjects and the study was approved by the ethics committee of the University Hospital of Lund.

THE NASAL POOL TECHNIQUE

The nasal pool-device is a compressible plastic container with a nasal adaptor. The adaptor is inserted into one nostril by the subject himself, sitting with his head flexed forward 60°. The container is compressed just to fill the unilateral nasal cavity. After 15 minutes the pressure on the nasal pool-device is released and the instilled nasal pool fluid is returned into the container. The exposed nasal mucosa is thus gently lavaged. Two additional quick lavages with isotonic saline are then carried out promptly. At the first visit the nasal pool fluid contained $^{51}$Cr EDTA...
Absorption of \( {^{51}}\text{Cr EDTA} \) across the human nasal airway barriers in the presence of topical histamine

Discussion

This study shows that the absorption of \( {^{51}}\text{Cr EDTA} \) across the human nasal mucosa is not affected by histamine. This agrees with data obtained in guinea pig tracheobronchial airways, where different exudative stimuli, including histamine, did not affect the absorption rate of luminal solutes. These findings may be important for our understanding of the role of plasma exudation in airway defence and in the pathogenesis of airway disease. Plasma exudation in the airways is not mentioned in current publications on respiratory defence. Plasma exudation into the airway lumen is generally thought to occur only in airways where the epithelial lining has been severely disrupted.

If, however, the potent protein systems in plasma can traverse the mucosa and operate on the airway surface without compromising the integrity of the epithelial lining as a barrier to solutes from the lumen, plasma exudation has to be ranked as a first line respiratory defence mechanism. A further inference is that plasma exudation into the lumen can occur in airway disease, even when there is no epithelial disruption and when absorption of material from the lumen remains normal.

Plasma exudation starts promptly after topical application of histamine and the response peaks within 10 minutes. Probably therefore plasma was being exuded throughout the 15 minutes during which absorption of \( {^{51}}\text{Cr EDTA} \) was being examined. We cannot exclude the possibility that histamine induced submucosal swelling (the blockage in this study) could have affected the absorption of \( {^{51}}\text{Cr EDTA} \) and the exudation of albumin. We think this is unlikely to be a major influence because the present data agree with findings in guinea pig airways, where exudation occurred without change in absorption and without producing detectable oedema. In addition, in human nasal experiments a vasoconstrictor drug reduced the histamine induced nasal blockage but not the exudation of albumin.

Acute mediator induced plasma exudation appears to be largely an unfiltered flow of different sized and different charged plasma solutes across the vascular endothelial wall and the mucosal epithelial lining. Thus the exudation of plasma in response to an inflammatory stimulus represents a major increase in the outward permeability of the airway barriers. Inward absorption permeability, however, may not increase, as suggested by previous studies in animals and the present results. Possibly a hydrostatic, pressure regulated, valve like mechanism may account for epithelial crossing of the plasma exudate that leaves absorption unaffected. This is suggested by animal studies in vivo and by in vitro observations that indicate that the epithelial lining has a normal appearance once the exudation process is complete.

\( {^{51}}\text{Cr EDTA (MW 372)} \) is a water soluble compound similar in size and character to technetium-99m labelled diethylenetriamine penta-acetate (DTPA) (MW 492), which has frequently been used to study bronchoalveolar absorption barriers in health and disease.
We selected $^{51}$Cr EDTA because it is stable, renal elimination can be measured after absorption,\textsuperscript{23} and any swallowed $^{51}$Cr EDTA would not affect the nasal absorption results appreciably.\textsuperscript{24} We confirmed previous findings\textsuperscript{24} that oral ingestion of $^{51}$Cr EDTA results in a 24 hour urinary excretion of radioactivity corresponding to only about 0.5% of the ingested dose.

Inhaled histamine has been shown to increase pulmonary clearance of $^{99m}$Tc DTPA.\textsuperscript{25,26} It is difficult to examine the human tracheobronchial barrier functions, however, with an acceptable specificity. The distribution of tracers and provocative agents cannot be controlled as closely as in nasal airways. It is also difficult to make a clear distinction between bronchial and alveolar barriers. Recent animal studies and a series of nasal experiments in man suggest that the barrier functions of nasal and tracheobronchial airways have important similarities.\textsuperscript{27} Thus the present data suggesting that exudative and absorptive permeabilities are separate are also likely to be applicable to the human tracheobronchial airways.

The present data, together with our previous findings with histamine, suggest that plasma exudation into the airway lumen is not necessarily associated with a change in the absorptive ability of the airway mucosa. A unidirectional increase in outward permeability is a potentially important respiratory defence mechanism but may also play a part in airway disease. The human nasal mucosa is readily accessible for quantitative and airway specific experiments and might prove an important site for further studies of the relation between inward and outward permeabilities of the airway mucosa.

The study was supported by grants from the Swedish Medical Research Council (projects 8508 and 2872).
