Transforming growth factor $\beta_1$ gene expression in human airways

John-David Aubert, Bakul I Dalal, Tony R Bai, Clive R Roberts, Shizu Hayashi, James C Hogg

Abstract

Background – Asthmatic airways have a characteristic deposition of connective tissue under the epithelial basement membrane, but the mediators involved in this alteration are unknown. Several authors have postulated that transforming growth factor $\beta_1$ (TGF-$\beta_1$) could be overexpressed in asthmatic airways.

Methods – Lung samples from 16 asthmatic patients, six patients with chronic obstructive pulmonary disease (COPD), and six non-obstructed smokers were analysed. RNA was extracted from these tissues to measure expression of TGF-$\beta_1$ by Northern blot analysis using a cDNA probe for TGF-$\beta_1$. The level of expression was quantitated by densitometry using glyceraldehyde 3-phosphate dehydrogenase mRNA as a control. TGF-$\beta_1$ was localised to specific cell types in these lungs by immunohistochemical analysis using polyclonal antibodies specific for intracellular and extracellular TGF-$\beta_1$.

Results – The 2.5 kb TGF-$\beta_1$ mRNA was seen in all 18 samples analysed by Northern blotting and densitometric analysis showed no difference between the asthmatic group (mean (SD) 108% (43%)), the group with COPD (122% (33%)), and the non-obstructed group (100% (49%)). The TGF-$\beta_1$ precursor was immunolocalised throughout the airway wall including the epithelium and in alveolar macrophages. The mature TGF-$\beta_1$ was localised primarily within the connective tissue of the airway wall. These patterns of expression of both forms of TGF-$\beta_1$ were similar in lungs from asthmatic patients, those with COPD, and controls.

Conclusions – While TGF-$\beta_1$ mRNA and protein are abundantly expressed in human lungs, there is no clear difference in expression between the airways of asthmatic subjects and those of smokers with and without COPD.

The airway wall from patients with asthma is thickened by an increase in the amount of several of its tissue components including smooth muscle, connective tissue, and mucus glands. In particular, connective tissue deposition beneath the epithelial basement membrane has been described. Together with type I, III, and V collagen fibres, the numbers of myofibroblasts containing $\alpha$-actin are increased. These findings are present even in patients with mild asthma, and seem to persist despite long term treatment with glucocorticoids. Airway wall thickening may have clinical significance in asthmatic subjects as it has been shown by mathematical modelling that an increase in the inner wall area can lead to exaggerated narrowing of the airway lumen with normal smooth muscle shortening.

Similar but less severe structural changes have also been reported in chronic obstructive pulmonary disease (COPD) associated with cigarette smoking. The biological factors responsible for the increased tissue mass in these diseased airways have not been identified, and the present study was designed to investigate the possible role of transforming growth factor $\beta_1$ (TGF-$\beta_1$) in the structural changes of the airway wall in patients with asthma and COPD.

Transforming growth factors are a family of growth regulators that play an important part in the metabolism of the extracellular matrix. They promote matrix protein synthesis, down regulate the proteolytic enzymes involved in matrix degradation, and increase the expression of receptors for extracellular matrix proteins. Based on these properties, the potential involvement of TGF-$\beta_1$ in the airways of asthmatic subjects has been hypothesised by several authors. Three closely related subtypes of TGF-$\beta_3$, TGF-$\beta_1$, TGF-$\beta_2$, and TGF-$\beta_4$, have been identified in mammalian species. These molecules all bind to the same heterodimeric receptor I-II on the cell surface and, although their biological activity is qualitatively similar, their expression is regulated through distinct pathways. TGF-$\beta_1$ is synthesised as a 390 amino acid latent precursor which is processed by proteolytic cleavage to a 112 amino acid molecule, by formation of disulphide bridges, yields a biologically active homodimer. Although activation from the latent precursor into the mature peptide can be achieved in vitro by proteases such as plasmin or cathepsin D, by an acidic environment, or by chaotropic agents, the mechanisms that control this activation in vivo are poorly understood.

As a first approach in analysing the potential role of TGF-$\beta_1$ in airway wall thickening, a survey of this growth factor in lung tissue from patients with asthma, COPD, and non-obstructed control patients was made. TGF-$\beta_1$, mRNA expression was measured by Northern blotting and the TGF-$\beta_1$ protein localised to specific cell types by immunohistochemistry in these samples. These data were then used to test the hypothesis that overexpression of

Methods

PATIENTS

The source of the tissue that formed the starting material for these studies is summarised in table 1. Twelve smokers undergoing lung resection for non-small cell carcinoma were part of an ongoing study of lung structure and function in this laboratory. This group was subdivided into non-obstructed smokers (n=6) and patients with COPD (n=6) according to a preoperative FEV1, above or below 80% of predicted, respectively. Lung tissue from these subjects was analysed by both Northern blotting and immunostaining. Four additional patients with COPD were selected for Northern analysis of peripheral lung versus segmental airways (not included in the table). For the asthmatic patients, because of the limited material available, simultaneous Northern analysis and immunohistochemical measurement was not feasible. Surgical specimens were obtained from four asthmatic patients with mild to moderate disease who required lung resection for non-small cell carcinoma (n=3) or a vascular malformation. Twelve necropsy cases, including 10 fatal asthma attacks, were also studied by Northern blotting (n=5) or by immunostaining (n=7).

The diagnosis of asthma was based on the criteria published by the American Thoracic Society and confirmed by examination of the pathological specimens. The histological criteria used to establish the pathological changes include those in the lumen (inflammatory mucous plugs), the airway epithelium (sloughing and goblet cell metaplasia), submucosa (vascular dilatation and inflammatory infiltrate dominated by eosinophils), and a markedly thicken smooth muscle layer. These changes also include a generalised increase in airway wall thickness compared with lungs of smokers.

Tissue processing

Lung specimens resected for non-small cell carcinoma from the 12 smokers with or without airflow obstruction, as well as from the three asthmatic patients, were processed as previously described by inflating them with a cryoembedding medium diluted 1:1 in saline (OCT, Miles, Elkhart, Indiana, USA), and freezing them over liquid nitrogen. Randomised peripheral samples 1.5 cm in diameter were cut out from an area remote from tumour and kept frozen at −70°C until they were analysed. The three specimens from the asthmatic patients were used only for immunohistochemical analysis. The additional surgical sample from an asthmatic subject was frozen without cryoprotective agent and used for Northern analysis. Lung tissue from the necropsy cases obtained within 24 hours after the time of death were either frozen without cryoprotective agent at −70°C (n=5) to be used for Northern analysis, or fixed in formalin and embedded in paraffin blocks (n=7) for immunohistochemical analysis.

NORTHERN BLOT ANALYSIS

Total RNA was extracted from 500 mg of lung parenchyma or lung tissue mainly comprised of central airways by the guanidinium thiocyanate phenol method using a tissue homogeniser (Polytron, Kinematica, Luzern, Switzerland). The RNA (20 μg) was separated by 0.7 mol/l formaldehyde, 1% agarose gel electrophoresis, and blotted onto nylon membranes (Hybond-N, Amersham, UK). After the nucleic acids were cross linked to the membranes by ultraviolet transillumination at 312 nm for four minutes, the filters were prehybridised four hours at 42°C in 0.75 mol/l NaCl, 50 mmol/l NaHPO4, 5 mmol/l Na2EDTA, 5 × Denhardt’s solution (100 × Denhardt’s = 2% BSA, 2% Ficoll 400, 2% polyvinylpyrrolidone), 0.5% (w/v) SDS, 50% (v/v) deionised formamide, 100 μg/ml yeast tRNA, and 10% (w/v) dextran sulphate. Hybridisation was performed for 18 hours under the same conditions with 1 × 106 cpm/ml 32-phosphorus labelled cDNA probe. The maximal stringency of the washes after hybridisation reached 0.1 × SSC (20 × SSC = 3 mol/l NaCl, 0.3 mol/l sodium citrate, pH 7.0), 0.1% SDS at 65°C. The filters were exposed to Agfa Curix Rp1 film (D) in the presence of an intensifying screen. The autoradiographic signal was quantified with the Ultrascan laser densitometer at 633 nm in the one dimensional mode and the GSXL...
TGF-β, in asthma and COPD

analysis software v.2.1 (Pharmacia LKB, Uppsala, Sweden). Care was taken to obtain film exposures in the linear range of the emulsion – that is, below 1.4 absorbance units. The filters were successively probed with TGF-β, and GAPDH cDNAs. To correct for unequal loading, data were expressed as the density of the TGF-β mRNA band divided by the density of the corresponding GAPDH mRNA band. GAPDH was chosen as an internal reference among other constitutive genes because its expression is not affected by TGF-β activity.30

ANTIBODIES

The antibodies to TGF-β used in our study, anti-LC (1–30) and anti-CC (1–30), were generous gifts from Drs K Flanders (National Institutes of Health, Bethesda, Maryland, USA) and L Ellingsworth (Celtrix Corporation, Palo Alto, California, USA), respectively. Both are polyclonal antibodies raised in rabbits against two different synthetic preparations of the same peptide sequence, corresponding to the first 30 amino acids of the N-terminal region of the mature TGF-β.31–33 Anti-CC (1–30) principally stains the extracellular matrix-bound TGF-β, whereas anti-LC (1–30), according to previous reports, stains the intracellular sites of TGF-β synthesis.31–34 Anti-LC (1–30) was used on cryostat sections, while anti-CC (1–30) was applied to formalin fixed tissue.

IMMUNOHISTOCHEMISTRY

As the necropsy lung tissue used for Northern analysis was frozen without a cryoprotective agent, the morphology was not preserved well enough for immunohistochemical studies. Other asthma cases were therefore studied, as outlined above. For anti-LC (1–30) staining cryostat sections, 6 μm thick, were placed on poly-l-lysine coated slides and briefly fixed in cold acetone. In the case of anti-CC (1–30) staining formalin fixed tissue embedded in paraffin, cut at 4 μm thick sections, was dried at 37°C overnight, deparaffinised and hydrated in sequential gradients of ethanol. Both paraffin and cryosections were immersed in 0.6% hydrogen peroxide (Sigma Chemicals, St Louis, Missouri, USA) in methanol for one hour to block endogenous peroxidase activity. For staining with anti-LC (1–30) the sections were incubated with 1 mg/ml hyaluronidase (Sigma) in 0.1 mol/l sodium acetate buffer, pH 5.5, at 37°C for 30 minutes, washed in distilled water, and then incubated with 5% skim milk powder for 30 minutes. The milk was drained off and the sections were covered with anti-LC (1–30) at a final concentration of 8–35 μg/ml, then with Parafilm, and incubated at 20°C. After two hours the slides were gently rinsed in Tris buffer and incubated with biotinylated goat antirabbit secondary antibody (Vector Laboratories, Burlingame, California, USA) at 20°C for 30 minutes. After washing the sections were returned to the humid chamber for incubation with peroxidase labelled streptavidin (Biocan Scientific, Westgrove, Pennsylvania, USA) at 20°C for 80 minutes. The slides were then stained with freshly prepared 3-amino-9-ethyl carbazole (Sigma) at 0.263 mg/ml for 10 minutes, counterstained with Meyer's haematoxylin, mounted with CrystalMount (Biomedia Corp., Foster City, California, USA), and covered-slipped. For staining with anti-CC (1–30) the same procedure was followed, except the hyaluronidase digestion was omitted and the primary antibody was used at a final concentration of 14 μg/ml. For negative controls the primary antibody was either replaced by non-immune serum or, in case of anti-LC (1–30), preincubated with TGF-β (1–30) blocking peptide (generous gift from Dr I Clark-Lewis, Biomedical Research Centre, Vancouver) at 15 μg/ml. The pattern of staining was recorded and compared with that of a positive tissue control of known intensity of staining (a para-neoplastic stromal reaction) which was included with every run. The samples were graded on a scale of − to + + +, according to the relative intensity of staining of each tissue.

DATA ANALYSIS

Because of the small sample size and the non-normal distribution of the data, the non-parametric Mann-Whitney and Kruskal-Wallis tests were used when required. In order to compare the results from the two Northern blots (fig 1) the samples from the non-obstructed smokers were run on both gels. Individual ratios of the optical density of the TGF-β band to that of the corresponding GAPDH band were then expressed as the percentage of the mean ratio measured for the non-obstructed control group on each respective blot. The same standardisation to the mean ratio of the control group was also used when comparing necropsy specimens with surgical specimens, and fatal with non-fatal asthma. For the Northern analysis of the central airways and the peripheral lung (fig 2) the mean ratio of the optical densities of the TGF-β band to that of the corresponding GAPDH band lane were compared. Unless otherwise specified results are expressed as mean (SD). A p value <0.05 was considered significant.

Results

Table 1 summarises the clinical data of the patients studied. The asthmatic lungs obtained at necropsy were, on average, from younger patients than the other groups. For the asthmatic patients the results of recent pulmonary function tests were available for only three of the cases where the material was obtained by surgical resection. In the necropsy group the cause of death was attributed to an asthma attack in 10 cases, the other two being a subarachnoid haemorrhage and coronary artery disease. Inhaled or oral glucocorticoids were known to be used by six of the 16 asthmatic patients and by none of the non-obstructed patients or those with COPD. Only three of the asthmatic patients were known to be active smokers.
NORTHERN ANALYSIS

The expected 2.5 kb band corresponding to TGF-β1 mRNA was detected in the 18 samples of peripheral lungs analysed (fig 1). Crossreactivity with either TGF-β1 or TGF-β2 subtypes was not observed, as the single signal detected did not correspond to the expected size of TGF-β1 or TGF-β2 mRNA. No major RNA degradation was seen as judged by ethidium bromide staining of the ribosomal RNA bands (data not shown) or on the autoradiographic signal from the TGF-β1 and GAPDH mRNA bands (fig 1). The quality of the mRNAs from the necropsy cases, of which three were asthma deaths, appeared indistinguishable from those obtained from surgical specimens. This was confirmed by the densitometric analysis of the intensity of the autoradiographic signals (fig 1, top panel) resulting in a mean (SD) of 108% (48%) for the necropsy group (n = 5) versus 101% (45%) for the surgical specimens (n = 7, p > 0.05).

Evaluation of TGF-β1 mRNA expression by densitometric analysis in the non-obstructed smokers (100% (49%)), patients with COPD (122% (33%)), and the asthmatic subjects (108% (43%)), after correction for unequal loading, showed no significant difference between these groups. To evaluate if the severity of the disease was correlated with the level of TGF-β1 mRNA, samples from the three fatal asthma cases were selected and compared with the three specimens from patients with mild to moderate non-fatal asthma. RNA expression was the same in the fatal asthma and in the non-fatal cases (96% (57%) versus 121% (31%), p > 0.05). To analyse TGF-β1 mRNA expression in different areas of the lung RNA from central airways (lobar, segmental, or sub-segmental bronchi) and lung parenchyma was extracted from another four patients with mild COPD (fig 2). TGF-β1 message was found in all eight samples and appeared to be more abundant in the peripheral lung in all four cases with a mean density of 1.107 (0.824) than in the airways with a mean of 0.418 (0.107) (p < 0.01).

IMMUNOHISTOCHEMISTRY

Immunostaining was analysed in airways with basement membrane lengths from 2.8 mm to 25 mm or shortest diameters of 0.2 to 5 mm. With the anti-TGF-β1, LC (1-30), immunostaining on cryostat sections detected the presence of the TGF-β1 precursor molecule in the bronchiolar epithelium, the submucosa, and in the airway smooth muscle (fig 3a and table 2). At a higher magnification the staining was observed to be more intense in the apical than the basolateral domain of the bronchial epithelial cell. In the peripheral lung the alveolar epithelium was not stained (fig 3b). Alveolar macrophages were usually positive but showed some heterogeneity in the intensity of staining (fig 3b). The blood vessels of the lung were also stained.

A second antibody, anti-TGF-β1, CC (1-30), which detects the mature and extracellular form of TGF-β1, was used on formalin fixed
Figure 3  Immunohistochemical detection of TGF-β, (bar = 40 μm).  
(a) Bronchiole from an asthmatic patient stained with the anti-LC (1–30) antibody.  
Red positive staining is observed in the apex of the epithelial cells and in the smooth muscle.  
(b) Lung parenchyma from a patient with COPD incubated with anti-LC (1–30).  
Alveolar macrophages are strongly positive whereas the alveolar epithelium is not stained.  
(c) Medium sized bronchus from an asthmatic patient stained with the anti-CC (1–30).  
The bronchial epithelium is not stained.  Strong reactivity is observed in the smooth muscle and in the connective tissue lying subjacent to the basement membrane.  
The basement membrane itself is not stained by the antibody.  
(d) Negative control of a small bronchiole where the primary antibody has been replaced by non-immune goat serum showing no reactivity.  
All sections are counterstained with haematoxylin.

Tissue. Almost no reactivity was found in the airway epithelium (fig 3c).  
Staining in the airway wall was observed at the site of extracellular matrix deposition and was especially intense in the submucosa and the smooth muscle (fig 3c).  
Examination of lung parenchyma showed that, in contrast to the staining with anti-TGF-β, LC (1–30) antibody, the alveolar macrophages were not stained by anti-CC (1–30).  
The alveolar epithelium was also negative.  
Negative controls showed minimal non-specific staining of the epithelial basement membrane and the submucosa (fig 3d).  
There was no difference in the pattern of reactivity and in the overall intensity of staining between the three clinical groups (control, patients with

COPD, and those with asthma either with the anti-LC (1–30) or the anti-CC (1–30) TGF-β1 antibodies. A summary of the results of antibody staining is given in table 2.

Discussion
This study shows that TGF-β1 mRNA and protein are expressed in the human lung. Northern blot analysis showed that a relatively abundant message can be detected in all samples examined. The immunohistochemical results revealed that the protein is present in the airway wall, including the epithelium, the submucosa, and the smooth muscle layer. In the parenchyma TGF-β1 is expressed only in the alveolar macropathies and in the blood vessels, but not in the alveolar epithelium. Both at the mRNA and at the protein level no difference could be found when the three clinical groups — non-obstructed, COPD, and asthmatic — were compared.

Northern blotting revealed a relatively abundant TGF-β1 mRNA in the 18 samples analysed. In addition, this study shows that human lung obtained at necropsy is a valid material for this type of analysis, without increased degradation of the RNA compared with that extracted from surgical specimens. Our data therefore suggest that TGF-β1 mRNA is abundant in the lung samples analysed. As asthma is primarily a disease of Airways it would have been ideal either to isolate mRNA from Airways tissue excluding parenchyma, or to localise the mRNA by quantitative in situ hybridisation. Neither of these approaches was open to us and we recognise that we are presenting data from a mixture of Airways and parenchyma. As both bronchoalveolar lavage and biopsy studies have shown that the changes in asthma are present in most peripheral Airways,35 it may be quite difficult to separate Airways from parenchyma in a satisfactory manner.

The two antibodies used in this study have been shown to recognise different epitopes of the TGF-β1 molecule, the anti-TGF-β1 LC (1–30) reacting with the peptide in the latent conformation, and the anti-TGF-β1 CC (1–30) reacting only with the mature homodimer bound to the extracellular matrix.37,38 It has been assumed, therefore, that the anti-TGF-β1 LC (1–30) staining reflects the site where this growth factor is being synthesised.31—33 Previous studies have shown that human alveolar macropathies are able to synthesise this growth factor in vitro36,37 and that epithelial lining fluid obtained by bronchoalveolar lavage from healthy volunteers contains high concentrations of TGF-β1.38 The cell types involved in the synthesis of this growth factor in vivo were not identified in this last study. Our results extend these findings by showing that the airway epithelium and the alveolar macropathies stain positively with the anti-TGF-β1 LC (1–30), while both are predominantly negative with the extracellular marker anti-TGF-β1, CC (1–30). These results suggest that both human airway epithelial cells and alveolar macropathies produce the latent form of TGF-β1 in vivo. Upon secretion into the extracellular space this latent form can be activated if the ad hoc chemical or enzymatic conditions are present to process the precursor into the mature form.

In the literature the study of TGF-β1 synthesis by the airway epithelium has yielded conflicting data. In mouse Airways29—30 the epithelial cells, although positive by immunohistochemical analysis, have not been shown to be positive by Northern blotting or by in situ hybridisation. This apparent paradox could be explained either by a lack of sensitivity of the in situ hybridisation technique or by a cross reactivity of the antibody with other subtypes of TGF-β or, less likely, by a selective transport of latent TGF-β1 from the submucosa through the epithelium. Contrary to our findings, Khalil and colleagues found no staining of the bronchiolar epithelium from non-fibrotic “control” human lungs using the anti-TGF-β1 LC (1–30).40 A possible explanation for this discrepancy is that the six non-obstructed control lungs analysed in our study were all from heavy smokers with non-small cell carcinomas. Although only non-tumour tissue was used in our study and no functional smoke induced abnormalities were found in these patients, one cannot exclude an abnormal inductions of TGF-β1 synthesis in the lungs of these individuals compared with true healthy controls. It should also be noted that in the initial characterisation of the anti-TGF-β1 LC (1–30) some cross reactivity with TGF-β3, or TGF-β2, although absent in ELISA studies, was not ruled out in immunohistochemical applications.31 Despite these conflicting results, one aspect of our present study is concordant with the two previous reports using the same antisera on human lung, namely, that the alveolar epithelium does not stain with anti-LC (1–30) antibody in control specimens.34,40 Together with the absence of staining in our negative controls, we therefore feel confident that the positivity of the airway epithelium for the latent form of TGF-β1 in the non-obstructed lungs is genuine.

Both at the mRNA and at the protein level we were unable to find any difference in TGF-β1 expression in lungs from asthmatic and COPD patients compared with non-obstructed lungs. A clear limitation of this study is the small number of patients and the heterogeneity of the asthmatic group. Despite this difficulty, because of the rarity of asthmatic tissue available, surveys such as this one...
are important since animal models never fulfill all the pathological features of human asthma. If TGF-β is involved in the pathogenesis of asthma, it would presumably be found in higher amounts in the more severe cases than in the mild ones. When we compared the mRNA levels from three fatal asthma cases with those of others with milder disease, however, no difference was observed. Drug treatment, especially with corticosteroids, could be a confounding factor in the analysis of these data. The increased expression of corticosteroids on TGF-β gene expression in vitro differ according to the cell type studied, with either an induction, a repression, or no detectable change. Limited evidence from studies in situ suggests, however, that in humans corticosteroid treatment has little effect on TGF-β mRNA expression in the lung. In our study the eight asthmatic patients known to be receiving either inhaled or oral corticosteroids did not differ from the other subjects in either their mRNA level or pattern of immunostaining for TGF-β.

The increased expression of the TGF-β gene was shown not to be in the cases of asthma and COPD reported here, the role of TGF-β in the pathogenesis of these conditions cannot be definitively ruled out. Many regulatory steps at the post-translational level are known to control TGF-β activity, notably the activation of the latent precursor, the binding to extracellular matrix components or to soluble receptors, as well as the inactivation through β1-microglobulin binding. One can therefore speculate that, in the airway microenvironment, local conditions might increase TGF-β bioactivity through one or several of these mechanisms. In addition, the potential involvement of other members of the TGF-β family, notably TGF-β and TGF-β2, remains to be ascertained. Finally, the recent cloning of the genes for type I and II receptors will facilitate studies to determine if the expression of these genes plays a regulatory role in controlling TGF-β activity in vivo.

In conclusion we have shown that TGF-β is expressed in the human lung both at the mRNA and at the protein level. TGF-β is localized mainly in the airway wall, including its epithelium, and in the alveolar macrophages. It does not appear to be overexpressed in the lungs of asthmatic and COPD patients. The subepithelial connective tissue deposition which is characteristic of asthmatic airways is therefore probably not the consequence of an abnormal synthesis of this growth factor.

We would like to thank Drs K. Flanders and J. R. Ellingsworth for providing the anti-TGF-β antisera, and Dr R. Derynck (Genentech, San Francisco) and Dr R. Morris (EPF, Montpellier, France) for the generous gifts of the human TGF-β, and the rat GAPDH cDNAs, respectively. We are also indebted to J. Chen and G. Harris for expert technical assistance, and to S. Green for photographic expertise.
