Relation between β-lactamase producing bacteria and patient characteristics in chronic obstructive pulmonary disease (COPD)

J H Sportel, G H Koeter, R van Altena, A Löwenberg, W G Boersma

Abstract

Background – In addition to bronchodilator and anti-inflammatory therapy, exacerbations in patients with chronic obstructive pulmonary disease (COPD) are often treated with antibiotics. Haemophilus influenzae and Moraxella (Branhamella) catarrhalis, two important respiratory pathogens, may produce β-lactamase which makes them resistant to ampicillin. Surveillance studies conducted in various countries have shown an increasing incidence of these β-lactamase producing bacteria. Although this may simply be a consequence of the increasing use of antibiotics, it is possible that other factors are important. A study was undertaken to investigate whether clinical factors are related to the presence of β-lactamase forming bacteria in the sputum of patients with COPD.

Methods – One hundred patients with COPD aged over 40 years were sequentially selected from an outpatient clinic on the basis of sputum culture results. Fifty had β-lactamase positive (βL+) and 50 had β-lactamase negative (βL−) bacteria in their sputum. Patients were included only if sputum culture results yielded one pathogen. The files of these patients were investigated for possible causative factors present during the two preceding years.

Results – Both groups were almost identical in terms of lung function, medication, and smoking history. The total number of antibiotic courses in the βL+ group was higher, as were individual courses of cephalosporins, tetracyclines, and macrolides. The number of patients admitted to hospital was higher in the βL+ group, but admissions were of equal duration in both groups. Patients admitted to hospital had poorer lung function. Risk factors for β-lactamase producing bacteria were identified by logistic regression analysis which revealed an odds ratio for one course of antibiotics of 1.15 (95% CI 1.04 to 1.28).

Conclusions – An increased number of antibiotic courses is related to a higher incidence of β-lactamase producing bacteria and more patients had hospital admissions in the βL+ group. β-lactamase stable antibiotics were used more frequently in the βL+ group, probably because prescribing was adapted to the presence of β-lactamase producing bacteria. No other differences were found between the βL+ and βL− groups.

Keywords: β-lactamase producing bacteria, chronic obstructive pulmonary disease.

Patients with chronic obstructive pulmonary disease (COPD) frequently have exacerbations, especially during the winter season. These exacerbations are characterised by increased dyspnoea, cough, sputum volume, and/or increased purulence of sputum. Patients with an exacerbation of COPD are usually treated with antibiotics as well as bronchodilators and corticosteroids. Although antibiotics should ideally be selected according to bacterial isolates, in general treatment is often empirical.

Since the late 1970s there has been an increasing incidence of respiratory pathogens resistant to ampicillin. In a European collaborative study resistance of Haemophilus influenzae to ampicillin varied from 0-5% in Austria to 31-1% in Spain. An American study reported an incidence of 20% of H influenzae strains resistant to ampicillin. Resistance to ampicillin for Moraxella (Branhamella) catarrhalis has been reported in up to 73% of cases. This resistance, due mostly to β-lactamase production, has a major impact on the efficacy of antibiotics in lower respiratory tract infection.

Beta-lactamases are enzymes produced by bacteria which inactivate β-lactam antibiotics by cleavage of the β-lactam ring. This is an oversimplification, since different types of β-lactamases and different types of spread and induction of β-lactamase can be recognised. The most important β-lactamase in H influenzae is TEM-1 β-lactamase which is transferred by plasmids. In M catarrhalis the most important β-lactamases are BRO-1 or BRO-2, whose origins remain unknown. The effect of the presence of β-lactamase is that an individual bacterium or the entire colony becomes resistant to β-lactamase unstable antibiotics.

One factor that could contribute to the increasing rate of β-lactamase producing bacteria in patients with COPD is antibiotic treatment which causes selection of resistant β-lactamase producing strains. However, other factors, related to the individual patient, might also contribute to the presence of β-lactamase producing bacteria. In this retrospective study we have investigated whether support could be found for this hypothesis.
Methods

PATIENTS
One hundred patients with COPD were selected from the pulmonary outpatient clinic of Hospital Beatrixoord, Haren, The Netherlands on the basis of sputum culture results, 50 patients with β-lactamase-producing bacteria (βL+ group) and 50 with bacteria that were not β-lactamase producing (βL− group). In all cases only a single pathogen was isolated, and patients were excluded when more than one pathogen was cultured. All patients were in a stable phase of their disease. Patients were over 40 years of age and none had a history of allergy. The patients’ files were retrospectively studied for the preceding two years to acquire data for the following characteristics: age, gender, duration of disease, smoking history, lung function, type and dosage of maintenance medication, hospital admission rate, and duration of hospital stay.

SPUTUM
Patients attending the clinic routinely delivered sputum in a sterile plastic jar at each visit. The sputum was washed three times in sterile saline to remove saliva and oropharyngeal flora. After Gram staining the sputum fragments were examined microscopically. When fewer than five epithelial cells and more than 25 leukocytes were counted per low power field (100 × magnification) the sputum was considered representative of the lower respiratory tract. Representative sputum specimens only were then cultured semiquantitatively according to accepted methods using blood agar, Leventhal’s agar, and McConkey’s medium, and incubated for 24 hours at 37°C. Susceptibility to antibiotics was tested by an agar dilution method using standard criteria. When resistance to ampicillin was shown an indicator test with nitrocephin (Cefinase, BBL Microbiology Systems, Becton Dickinson and Co, Cockeysville, USA) was applied for detection of β-lactamase activity.

LUNG FUNCTION
During the consultation inspiratory vital capacity (IVC) and forced expiratory volume in one second (FEV1) were measured twice in a standard manner using a Pneumoscope (Jaeger, Breda, The Netherlands). Measurements were made at least four hours after any inhaled bronchodilators. The higher results of both IVC and FEV1 were used.

DURATION OF DISEASE
The duration of disease was calculated by subtracting the date on which the patient was diagnosed as having COPD from the date of the visit to the outpatient clinic.

MAINTENANCE MEDICATION
Information on maintenance treatment was retrieved from the next to last letter addressed to the general practitioners; the type of medication as well as the daily dosage in mg per day was noted.

NUMBER OF ANTIBIOTIC COURSES
The patients’ general practitioners and pharmacists were telephoned in order to assess the number and type of antibiotic courses that had been prescribed. Data on antibiotic courses prescribed by respiratory physicians were derived from the hospital files.

SMOKING
The following definitions were used: “non-smokers” were patients who had never smoked; “ex-smokers” were patients who stopped smoking before the beginning of the study period. Exposure was expressed as pack-years.

ADMISSIONS TO HOSPITAL
The admission rate was assessed by counting the number of hospital admissions in the two years preceding the visit to the outpatient department. The duration of each admission and the total duration of all admissions in these two years were noted.

STATISTICAL ANALYSIS
The Student’s t test was used for normally distributed variables, the Mann–Whitney U test for not normally distributed and categorical variables, and the χ² test for dichotomous variables. The statistical software package SPSS/PC+, V4.0.1 (SPSS Inc, Chicago, Illinois, USA) was used. Logistic regression analysis was performed to build a model that could predict the presence of β-lactamase-producing bacteria. For this and for computation of odds ratios and confidence intervals the computer program Statistix (Analytical Software, St Paul, Minnesota, USA) was used. Variables that would not fit in the model according to known criteria were forced into the model when they seemed biologically important. A p value of <0.05 was considered significant.

Results
The patients analysed in this study were enrolled over a period of 20 consecutive months. During this period 1843 individual patients visited the outpatient clinic at least once, of whom 580 (31%) produced sputum. Sputum was cultured on 960 occasions and revealed pathogens in 389 (40%) of cultures. Of the enrolled patients, all produced sputum chronically, most had airflow limitation, and 60% were smokers.

SPUTUM
The results of sputum cultures are summarised in table 1; 77 of 100 isolates contained H influenzae or M catarrhalis. β-lactamase-producing strains were found in 33 of 42 (79%) M catarrhalis strains and five of 35 (14%) H influenzae strains.
PATIENT CHARACTERISTICS
Both patient groups were comparable for most characteristics (table 2). Significantly more patients in the βL+ group had been admitted to hospital in the preceding two years, but the total number of admissions and the duration of those admissions were similar. Patients who had been admitted once or more in the past two years used more antibiotic courses (median range) 10 (2-25) with a total of 262 courses to the 27 patients admitted compared with 3 (0-20) with a total of 323 antibiotic courses to the 73 not admitted. The patients admitted to hospital had poorer lung function (both FEV1% pred and IVC% pred p ≤ 0.005). There were no differences between the βL− and βL+ patients who had been admitted with regard to their number of antibiotic courses or their lung function.

ANTIBIOTIC TREATMENT
There was a wide interindividual range in the number of antibiotic courses during the two year period (table 4). More antibiotic courses were used by patients in the βL+ group (p = 0.005) and this applied to cephalosporins (p < 0.05), tetracyclines (p < 0.05), and macrolides (p < 0.005). The individual patients in the βL+ group also had more courses of tetracycline than those in the βL− group (p < 0.005). Thirteen patients were on maintenance antibiotic treatment, eight in the βL+ group and five in the βL− group (NS).

*p < 0.05, χ² test; **p < 0.005, Mann-Whitney U test.
Penicillins and cephalosporins were divided into β-lactamase stable and unstable antibiotics. No differences were found for β-lactamase stable and unstable penicillins, and β-lactamase unstable cephalosporins. β-lactamase stable cephalosporins were used by more patients in the βL+ group (p<0.05).

β-lactam antibiotics were not used more often for the last course than non-β-lactam antibiotics.

### Logistic Regression Analysis

It appeared that few variables would fit the model. The results of our analysis (odds ratios (OR) and 95% confidence intervals (CI)) are shown in Table 5 in which are also displayed OR and CI for 10 antibiotic courses. A higher number of antibiotic courses in the past two years increased the chance of having a β-lactamase-producing bacterium in the sputum.

### Discussion

*Streptococcus pneumoniae, H influenzae, and M catarrhalis* are known to be major respiratory pathogens in COPD. In this study *H influenzae* and *M catarrhalis* were also the most frequently isolated single pathogens, in frequencies similar to those of other studies. The same is true for the frequency of *Streptococcus pneumoniae* (20%). By selection bias *Streptococcus pneumoniae* was only included in the βL− group. Resistance of *Streptococcus pneumoniae* to ampicillin is not associated with β-lactamase but is caused by changes in penicillin binding proteins.

The prevalence of resistance of airway pathogens, especially *H influenzae* and *M catarrhalis*, is increasing, mainly because of β-lactamase which causes resistance to ampicillin. In 1989 surveillance cultures performed in the same study population yielded *H influenzae* in 57% (βL+ 9%), *M catarrhalis* in 23% (βL+ 57%), and *Streptococcus pneumoniae* in 21%. In this study we confirm that this increased resistance is associated with the increased use of antibiotics. We have considered the possibility that patient related factors may also contribute to this resistance.

In the present study more antibiotic courses were taken by patients in the βL+ group than by those in the βL− group. Patients who had been admitted, both in the βL− and βL+ groups, had poorer lung function and had received more antibiotic courses than the others. This may be explained by the fact that patients with poor lung function seem to suffer more severely during exacerbations. Thus, respiratory physicians and general practitioners prescribe antibiotics and admit their patients more readily than when lung function is better.

The fact that more patients in the βL+ group used tetracyclines and βL stable cephalosporins, and that more courses of tetracyclines were used in the βL+ group, can be explained as follows. We found that the sputum culture results were mentioned in most correspondence to general practitioners and these were noted, resulting in the prescription of an effective antibiotic. An alternative explanation could be that general practitioners and respiratory physicians noticed poor results from empirical antibiotic prescribing, and that βL stable antibiotics had a favourable effect. However, we would then have also expected more β-lactamase sensitive antibiotics to have been prescribed. It is known that there is a wide interindividual range in the frequency of exacerbations, thus patients in the βL+ group were more likely to have a higher frequency of exacerbations. If this did occur the reason for it remains unclear, although various explanations are possible – for example, a greater bronchial hyperresponsiveness or, for some reason, less optimal anti-COPD treatment with corticosteroids and/or bronchodilators.

The higher frequency of exacerbations in the βL+ group eventually results in the use of more courses of antibiotics. However, with frequent usage of antibiotics β-lactamase producing bacteria are being selected and, in studies in children with upper and lower respiratory tract infections caused by *H influenzae* both type b and non-b, more resistant strains were found in those who had recently been treated with antibiotics. In neither study were patients suffering from any underlying disease, and the study period lasted up to seven weeks. Although these studies are not strictly comparable with the present report on older patients with COPD who were studied retrospectively for two years, the findings are similar to ours – that is, increasing use of antibiotics is related to isolation of more β-lactamase producing strains. This is also supported by the results of our logistic regression analysis. Some studies have also shown that there is a relation with the type of antibiotic prescribed, which is in contrast to our findings. Wallace *et al* studied *H influenzae* resistance to ampicillin, tetracycline, and chloramphenicol in adults with chronic lung disease. Their results showed that patients with resistant strains were more likely to have received antibiotics recently.

The presence of β-lactamase producing bacteria may be considered as an end point in a pathogenetic chain, in parallel with the colonisation of the respiratory tract in patients with cystic fibrosis or severe bronchiectasis by *Pseudomonas aeruginosa*. It is, however, possible that the presence of β-lactamase producing strains is a cause, rather than a consequence, of the higher exacerbation rate. One could speculate that this would imply that β-lactamase producing strains from the same species present a more virulent biological behaviour than non-β-lactamase producing strains.
spective studies are needed to test these hypotheses.

We are aware of certain drawbacks of this retrospective study. Firstly, the maintenance medication was assessed only at the end point of the study period and we have no information on previous changes of treatment or compliance. Secondly, we do not know the exact dosage and duration of the antibiotic courses, nor do we know what criteria were used for prescribing antibiotics or whether they were prescribed in combination with prednisolone. Thirdly, the lung function tests may not have been representative of the entire two year period. Data on decline in lung function and reversibility were not available for all patients. Fourthly, and more importantly, we do not know if the sputum culture results are representative for the whole two year period. From other studies we think that in most patients they were since it has been shown that the same bacteria can be isolated from the sputum for a long period. Finally, by screening for clinically suggestive characteristics we were not able to identify reliably patients with bronchectasis. Objective measures (high resolution computed tomographic scanning and bronchography) for the diagnosis of bronchectasis were not available in most files. However, we would have expected patients with bronchectasis to be distributed equally between both groups, and the number of patients with extensive bronchectasis is likely to be very low.

In conclusion, we have shown that more frequent antibiotic use is associated with a higher chance of the presence of β-lactamase producing bacteria in the sputum of patients with COPD. A prospective study is necessary to confirm our data and hypotheses. In such a study other factors such as changes in maintenance medication, the causal stimuli of exacerbations, bronchial hyperresponsiveness, and the extent of anatomical destruction of Airways and lung tissue need to be analysed.

Since we need to prevent any further increase in the prevalence of resistance to antibiotics, not only due to β-lactamase production, we should be aware of the risks in prescribing them. Patients with a high exacerbation rate should be identified and efforts made to prevent them. However, when antibiotic treatment is considered imperative it should be given on a valid indication. Adequate microbiological identification and assessment of antibiotic resistance are desirable parameters, on the basis of which optimum antibiotic treatment can be initiated.
