Expiratory muscle training and sensation of respiratory effort during exercise in normal subjects

Shunsuke Suzuki, Masamichi Sato, Takao Okubo

Abstract

Background -- The sensation of respiratory effort may increase as expiratory muscles become fatigued during expiratory loading. A study was performed to determine whether expiratory muscle training (EMT) affects the sensation of respiratory effort during exercise in healthy subjects.

Methods -- Six subjects performed EMT for 15 minutes twice daily for four weeks using a pressure threshold device; another six subjects served as a control group. The expiratory threshold was set at 30% of the individual's maximum expiratory mouth pressure (Pemax). The sensation of respiratory effort was evaluated during a progressive exercise test using the Borg scale.

Results -- After EMT PEmax increased by 25% in the training group. The Borg score increased as exercise grade increased before and after EMT, but scores for each grade were lower after EMT. Minute ventilation during exercise decreased after EMT, as did the breathing frequency during exercise, while the expiratory time increased. Although there was no difference in the relationship between Borg score and minute ventilation before or after EMT, the curve shifted to a lower Borg score after EMT. There were no changes in PEmax, Borg score, minute ventilation, or breathing pattern after the four week study period in the control group.

Conclusion -- These findings suggest that EMT increases expiratory muscle strength and reduces the sensation of respiratory effort during exercise, presumably by reducing minute ventilation.

Methods

Twelve healthy volunteers (10 men, mean [SD] age 30.0 [5.5] years, range 24 to 44) took part in the study. All were non-smokers with no history of chronic respiratory or circulatory disease. Subjects were randomly assigned to control (n = 6; 5 men) or training groups (n = 6; 5 men). Informed consent was obtained from each subject. The study was approved by the committee on human investigation of our institution.

On test days subjects were prohibited from drinking coffee or other caffeine-containing beverages. Spirometric measurements were performed using a dry seal spirometer (OST-80, Chest Co, Tokyo, Japan), and vital capacity...
Breathing effort and respiratory training

(VC) and forced expiratory volume in one second (FEV,) were measured. The maximal voluntary ventilation (MVV) was determined from maximal voluntary ventilation over a 15 second period. Lung volumes were measured using a body plethysmograph (Autobox 2800, Gould, Dayton, Ohio, USA).

MAXIMUM RESPIRATORY PRESSURE
Maximum static inspiratory and expiratory mouth pressures (PIMax and PEMax) were measured according to the method of Black and Hyatt. Briefly, mouth pressure was measured using a differential pressure transducer (Validyne MP-45 ± 250 mm Hg, Northridge, California, USA). PIMax was determined from the maximal inspiration against a closed valve at functional residual capacity (FRC) and residual volume (RV). PEMax was determined from the maximal expiration against a closed valve at FRC and total lung capacity (TLC) while subjects pressed their cheeks with their hands. They practised these pressure measurements two days before baseline measurements were obtained (control day) to reduce any learning effect. On test days PIMax and PEMax were measured at least three times until a reproducible value was obtained and maximum values were reported.

RESPIRATORY EFFORT DURING EXERCISE
Respiratory effort during exercise was evaluated by a modified Borg scale. This scale consists of a series of integers from 0 to 10. The subject was told to estimate the effort required to produce each breath, but not shortness of breath or the effort of exercise. During exercise the Borg scale was kept in front of the subject who was asked to rate effort at one minute intervals.

EXERCISE TEST
A progressive exercise test was performed on a treadmill (Quinton Q50, Seattle, Washington, USA). Each subject breathed air through a two-way non-rebreathing valve (No. 2700, Hans Rudolph, Kansas City, Missouri, USA) so that concentrations of expired gas and ventilation could be measured. Expired gas was sampled and analysed breath by breath. Tidal volume (VT), breathing frequency, minute ventilation (VI), oxygen uptake (VO2), output of carbon dioxide (VCO2), and dead space/tidal volume ratio (Vd/VT) were determined using the 2900 Energy Measurement System (Sensormedics, Anaheim, California, USA). Inspiratory time (TI) was calculated from the flow signal. The Vd/VT was determined using the Bohr equation. Arterial oxygen saturation was measured with a pulse oximeter (Biox 3740, Ohmeda, Boulder, Colorado, USA). An electrocardiogram was monitored throughout the experiment.

A modified Balke exercise protocol was used. The workload was increased by approximately 1 met (metabolic equivalent of resting O2 uptake) at one minute intervals. At stage 1 the treadmill was kept at a constant speed of 2.0 mph and the grade at 0%. Beginning at stage 2, the grade was increased from 0% by 2.5% at one minute intervals—that is, one stage per minute—up to stage 10, and the speed was kept at a constant 3.3 mph. The exercise test was continued until the subject reached a state of exhaustion or stage 10 with a slope of 20%.

EXPIRATORY MUSCLE TRAINING (EMT)
Subjects in the training group trained with a threshold pressure breathing device (Threshold Inspiratory Muscle Trainer, Healthscan Products, Cedar Grove, New Jersey, USA) that uses a spring loaded poppet valve. We modified its spring to produce pressure loads ranging from 15 to 125 cm H2O. This device is designed primarily for inspiratory muscle training. We modified the conventional method of using the device by asking the subjects to expire through the opposite side of the device. The threshold pressure used was equal to 30% of the individual's PEMax at TLC before EMT and was kept constant throughout the four week training period. Subjects were instructed to expire air twice daily through the threshold device at their own breathing frequency and tidal volume for 15 minutes and to record their execution of EMT.

EXPERIMENTAL PROTOCOL
No other form of exercise training was started during the four week study, and all subjects maintained their usual habits during the study period. On day 1 spirometric parameters, lung volumes, PIMax, and PEMax were determined to obtain baseline values. The sensation of respiratory effort was measured during the treadmill exercise test. After two weeks of EMT, PIMax and PEMax were measured, and spirometric measurements and the exercise test were repeated. After four weeks of EMT spirometric measurements were again made, and lung volumes, maximum respiratory pressures, and the sensation of respiratory effort were determined during exercise.

DATA ANALYSIS
All values were reported as the mean (SD). Differences in respiratory muscle strength between groups were analysed by the unpaired t test.19 Spirometric values and respiratory muscle strength before and after EMT were analysed by the paired t test. The Borg score was analysed using Friedman's test. Ventilation parameters were analysed using two-way analysis of variance with repeated measures (ANOVA), followed by post hoc comparison using the Tukey's test. A p value of less than 0.05 was considered statistically significant.

Results
All subjects in the training group completed the study. Vital capacity, FEV1, lung volumes, and MVV did not change over the four week
control day values at two weeks (average 20-0%) and four weeks (from 165(71) to 202(77) cm H₂O; average increase 25-4%) (p<0-01) (fig 1). Pmax at FRC increased by 20-2% after two weeks of EMT (p<0-01) and by 18-2% after four weeks (from 143(65) on the control day to 168(72) cm H₂O, p<0-05). Individual differences in Pmax did not change after EMT. Pmax did not change at RV or FRC. There were no significant changes in Pmax or Pimax at any lung volume in the control group.

All subjects completed the exercise test to stage 10 on both the control day and after four weeks, and consequently the exercise test was submaximal exercise. Before EMT the Borg score increased linearly with time in both groups (r=0-96(0-05) and 0-97(0-04) for the control and training groups, respectively) (fig 2). On the control day there was no significant difference between the two groups in the Borg score at any stage of exercise. After EMT the Borg score was significantly lower than the control day at each exercise stage (fig 2, p<0-01). In the control group the Borg score did not change significantly at any exercise stage during the four week study period. The slope of the Borg score with time (or exercise stage) decreased from 0-63 (0-17) ml min⁻¹ to 0-43 (0-22) ml min⁻¹ at four weeks (p<0-05) in the training group, but did not change in the control group.

Minute ventilation (VE) increased with exercise stage in both groups (fig 3). In the

Breathing effort and training

Expiratory period during exercise (Fig 4).

Figure 4 (A) Breathing frequency and (B) expiratory time (T_e) during exercise of control and training groups on the control day (○,△) and after the four week study period (●,▲). Expiratory muscle training reduced breathing frequency (p<0.05; ANOVA) and increased T_e (p<0.05; ANOVA), although the T_e decreased with exercise stage in the control group. *p<0.05; †p<0.01 compared with control day (Tukey’s test). Values are mean (SE).

In the training group VE was significantly lower after EMT than on the control day (p<0.05, ANOVA). VT did not change in the control group. The VT increased with exercise stage in both groups and did not change after EMT. Breathing frequency increased with exercise in both groups (fig 4). In the training group breathing frequency was lower after EMT compared with the pre-EMT value (p<0.05, ANOVA). The expiratory time (T_e) decreased with exercise stage in both groups (fig 4). In the training group the T_e increased after EMT (p<0.05, ANOVA). In the control group there was no significant difference in T_e between the control day and the four week values. The Vd/VT decreased with increasing exercise stage. There was no difference in Vd/VT between the control day and the four week values in either group. VO_2 and VCO_2 increased progressively with exercise in both groups. VO_2 and VCO_2 tended to decrease after EMT, but the difference was not significant. The ventilatory equivalent for oxygen (VE/VO_2) decreased towards the midpoint of the exercise protocol and then increased in both groups. EMT reduced VE/VO_2 in the second half of the exercise protocol (p<0.05). There was no change in arterial oxygen saturation during exercise on both the control day and after four weeks in either group.

The Borg score and VE were closely correlated in all subjects on each test day (0.89<r<0.99). The relationship between the Borg score and the VE was similar on the control day and after four weeks in both groups.

Discussion

We have shown that a four week period of EMT using a pressure threshold device increased the strength of the expiratory muscles and reduced the sensation of respiratory effort during exercise in normal subjects. The relation of the sensation of respiratory effort to VE was not changed by EMT, although the sensation of respiratory effort and VT decreased after EMT at each exercise stage, suggesting that EMT diminishes the sensation of respiratory effort during exercise by reducing VE.

EXPIRATORY MUSCLE TRAINING (EMT)

Leith and Bradley demonstrated that ventilatory muscle training increased ventilatory muscle strength. Inspiratory muscle training has been attempted in patients with COPD, but no previous study has investigated the effect of EMT using expiratory loading. In the present study EMT was performed using pressure threshold loading at 30% of the subject’s P_{max} at TLC. All subjects in the training group showed an increase in P_{max} after EMT. We expected that an increase of this magnitude in expiratory muscle strength would allow us to examine the effects of strengthening of respiratory muscles on the sensation of respiratory effort.

SENSATION OF RESPIRATORY EFFORT DURING EXERCISE

While patients with COPD experience breathlessness more intensely during inspiration, the sensation generated during exercise in normal subjects is more intense during expiration. During exercise expiratory muscles, especially the abdominal muscles, contribute substantially to increased ventilation, although the work of inspiratory muscles also increases. The sensation generated during exercise is closely related to factors that contribute to respiratory muscle effort such as increased ventilation. Minute ventilation represents the overall output of the respiratory system. During exercise consistently linear relationships have been observed between VE and the intensity of breathing-related sensation in normal subjects.

In the present study the relationship between Borg score and VE did not change over four weeks in either study group, suggesting that VE may be one of the most useful parameters for evaluating the sensation of respiratory effort during treadmill exercise.

EFFECT OF EMT ON THE SENSATION OF RESPIRATORY EFFORT

We expected that an enhancement of expiratory muscle strength would reduce the fraction of expiratory muscle force needed for a given
amount of work, which would reduce the magnitude of the central motor command to expiratory muscles, thereby reducing the sensation of respiratory effort. If a decrease in the fraction of expiratory muscle force during expiration directly affected the sensation of respiratory effort, the relationship of Borg score to \( V_E \) would have been changed by EMT. In the present study the relationship of Borg score to \( V_E \) was unchanged by EMT, although expiratory muscle strength was increased by EMT. We therefore concluded that an increase in expiratory strength may not directly affect the sensation of respiratory effort during exercise.

Abdominal muscles, which are major expiratory muscles, were trained by EMT in the subjects studied. In addition to contributing to expiration, abdominal muscles work to stabilise the body position during exercise. It is possible, therefore, that EMT may reduce the \( V_O \) of the abdominal muscles for both these functions during exercise. Also, physical training is known to reduce both \( V_E \) and \( V_O \) of whole body. A reduction in \( V_E \) may reduce the sensation of respiratory effort at each exercise stage.

In the present study EMT altered breathing patterns, such as breathing frequency, \( T_e \) and \( V_t \). The \( T_e \) decreased with increasing exercise stage in the control group but increased after EMT in the training group. Burdon and co-workers showed that, during exercise, the breathing frequency increased; the \( T_e \) showed a greater decrease than the inspiratory time. In our study EMT may have increased \( T_e \) during breathing through expiratory loading to reduce the difficulty of breathing because subjects were asked to perform EMT using their own breathing patterns. Belman and co-workers showed that a change in breathing pattern improved ventilatory muscular performance. Thus, our subjects may have learned a breathing strategy that lengthened \( T_e \) in the presence of increased work of breathing. A decrease in breathing frequency associated with lengthened \( T_e \) may reduce \( V_E \). However, EMT altered the relationship of Borg score to \( T_e \) and the breathing frequency. These findings suggest that the EMT-induced change in breathing pattern may not directly affect the sensation of respiratory effort during exercise.

Although EMT produced no change in \( V_E/ V_t \), it reduced the equivalent for oxygen (\( V_E/ V_O \)), suggesting that it enhanced the effectiveness of ventilation during exercise. Increases in \( T_e \) and \( P_{max} \) may permit the expiratory muscles to play a major part in expiration during exercise, lengthening the diaphragm and improving the length-tension characteristics for generation of pressure required to produce a subsequent inspiration. Thus, EMT may improve diaphragmatic function, reducing the sensation of respiratory effort.

In conclusion, expiratory muscle training reduces the sensation of respiratory effort during exercise in normal subjects, although the exact mechanism of this effect is unclear. Before this expiratory muscle training programme can be applied to patients with respiratory disease, the effect of EMT on breathlessness should be investigated in a modified programme for patients.
